THE DEVELOPMENT OF THE ACADVL SCANNING ASSAY USING A TWO-STEP PCR
AND HIGH RESOLUTION MELTING ANALYSIS

by

Nadia Benkhadra

A thesis

Presented to the faculty of

Towson University

in partial fulfillment

of the requirements for the degree

Master of Science in Forensic Science

Towson University
Towson, Maryland 21252
May 2014

**TOWSON UNIVERSITY
OFFICE OF GRADUATE STUDIES**

THESIS APPROVAL PAGE

This is to certify that the thesis prepared by Nadia Benkhadra entitled The Development of the ACADVL Scanning Assay using a Two-Step PCR and High Resolution Melting Analysis has been approved by the thesis committee as satisfactorily completing the thesis requirements for the degree Master of Science in Forensic Science in the Department of Chemistry.

ACKNOWLEDGEMENTS

First, I would like to thank my supervisor, Dr. Leka Papazisi, for teaching me everything I needed to know about how to develop an assay and how to optimize the assay using specific techniques. He provided me with direction during this project and constant support and encouragement. I could not have completed this without him. I would also like to thank Dr. Jarkko Huuskonen, Dr. Renee Howell and Dr. Ivor Knight for their unwavering support throughout this process. This would not have been possible without them. I would like to thank my colleagues at Canon US Life Sciences. I learned an immense amount from the work they had previously done, which helped me to complete my project. Last but not least, to Dr. Zeller, my faculty advisor, I would like to thank you for helping this come to fruition and answering my endless number of questions.

ABSTRACT

The Development of the ACADVL Scanning Assay using a Two-Step PCR and High Resolution Melting Analysis

Nadia Benkhadra

Very long chain acyl-CoA dehydrogenase deficiency is the second most common fatty acid oxidation disorder detected by newborn screening. Currently, tandem mass spectrometry is used as the primary detection method, followed by molecular genetic testing to confirm the presence of a mutation. A simpler, more cost effective method of diagnosis is high resolution melting (HRM) following amplification of the target. HRM does not require physical processing or separation steps. In this study, PCR primers' that amplify each of the 20 exons that make up the *ACADVL* gene were designed. One primer pair for each exon was selected based on PCR performance and target specificity. After defining the PCR cycling conditions, we performed a blinded study with 30 different genomic DNA samples. Synthetic constructs were used as positive controls for each test. Seven different mutations were detected from the high resolution melting profiles. Bi-directional DNA sequencing (Sanger Sequencing) confirmed the mutations.

CHAPTER I

BACKGROUND

The body requires constant sources of fuel to perform every day functions. Its source of energy depends on the availability of certain molecular resources. Two important sources of energy are carbohydrates and fatty acids. Carbohydrates, such as glucose, are an important source of energy in the body, but fatty acids are able to store much more energy per gram (Croston, 2001). They are major sources of energy for the heart and muscle. The brain also uses fatty acids as a source of fuel in addition to glucose and ketone bodies. During periods of fasting, they serve as important energy sources for the liver and other tissues as well. In the adipose tissue, fatty acids are stored in the form of triglycerides, which consist of three fatty acid molecules and one glycerol molecule (Croston, 2001). When glucose levels are low, usually during periods of fasting, glucagon, an enzyme secreted by the pancreas, initiates adipose tissue lipase activity (Croston, 2001). This enzymatic activity triggers the hydrolysis of triglycerides and the release of fatty acids. The “free” fatty acids travel through the blood via albumin and lipoproteins to other tissues such as muscle and are oxidized to provide energy via the mitochondrial beta oxidation pathway. Short and medium chain fatty acids of less than 10 carbons are able to cross the outer and inner mitochondrial membranes to enter the mitochondrial matrix (Tein, 2002). However, the mitochondrial membrane is impermeable to long-chain fatty acids (Tein, 2002). Fatty acid beta oxidation occurs in the mitochondrial matrix, which requires long chain fatty acids to be transported from the cytoplasm of the cell, across the mitochondrial membrane. The transport of long chain fatty acids into the mitochondria is accomplished by the

enzyme carnitine palmitoyl transferase I , which is located on the inner membrane (Croston, 2001) (Tein, 2002).

The beta oxidation pathway is a series of four reactions (**Figure 1**). The first reaction, catalyzed by the enzyme acyl-CoA dehydrogenase, is a dehydrogenation, or oxidation, reaction that introduces a trans C=C bond between the alpha and beta carbons of the fatty acyl CoA molecule using a mechanism that reduces membrane bound FAD to FADH₂ (Miesfeld D. , 2008). After oxidation is complete, enoyl-CoA hydratase catalyzes the hydration reaction. This enzyme adds H₂O across the C=C bond to convert trans-delta2-enoyl-CoA to 3-L-hydroxyacyl-CoA. In the third reaction, beta-hydroxyacyl-CoA dehydrogenase removes an electron pair from the substrate and donates it to NAD⁺ to form NADH (Miesfeld, 2008). The final step in the beta-oxidation pathway is a thiolysis reaction which is catalyzed by the enzyme acyl-CoA acetyltransferase, also known as thiolase. During this step, a molecule of acetyl-CoA is released and a fatty acyl-CoA product that is two carbons shorter than the starting substrate is produced (Miesfeld, 2008). These reactions occur in repeating cycles with each fatty acid molecule until consumed. During each cycle, the fatty acid molecules are oxidized and shortened by two carbons. The energy released is captured by the reduced carrier molecules NADH and FADH₂. At the end of each four reaction cycle, a two-carbon acetyl-CoA molecule is released from the end of the fatty acid. The fatty acid molecule continues through another round of beta oxidation until all even chain fatty acids are oxidized to acetyl-CoA. The number of acetyl-CoA molecules produced depends on the carbon length of the fatty acid being oxidized (Miesfeld, 2008).

Very long chain acyl-CoA dehydrogenase (VLCAD) belongs to a family of acyl-CoA dehydrogenase (ACAD) flavoenzymes that catalyze the alpha-beta-dehydrogenation of acyl-CoA

esters using the electron transfer flavoprotein (ETF) as their electron acceptor. There are four highly homologous, straight chain acyl-CoA dehydrogenase enzymes with differing chain lengths which catalyze this first step: very long chain acyl-CoA dehydrogenase (VLCAD; uses C14-C20 fatty acyl-CoAs), long chain acyl-CoA dehydrogenase (LCAD; uses C10-C14 fatty acyl-CoAs), medium chain acyl-CoA dehydrogenase (MCAD; uses C6-C10 fatty acyl CoAs), and short chain acyl-CoA dehydrogenase (SCAD; uses C4-C6 fatty acyl-CoAs). All acyl-CoA dehydrogenase enzymes, except VLCAD, are mitochondrial matrix associated homotetramers composed of monomers that are nearly identical in size (~40kDa). VLCAD is a homodimer consisting of 70 kDa subunits associated with the inner mitochondrial membrane. It has an additional 180 amino acids at its carboxy terminus which facilitates its interaction with the inner mitochondrial membrane and other fatty acid oxidation proteins (Schiff, et al., 2013).

There are a number of specific enzyme deficiencies associated with fatty acid oxidation, one of which is very long chain acyl-coenzyme A dehydrogenase deficiency (VLCADD). VLCADD is an autosomal recessive inherited disorder that affects the first step in the beta oxidation pathway (Olsen, et al., 2010). In VLCADD, enzymatic deficiency causes the accumulation of long-chain acylcarnitine, with C14:1-carnitine as the disease specific marker (Schymik, et al., 2006). Deficiency in this gene product reduces myocardial fatty acid beta-oxidation and is associated with cardiomyopathy. While the pathology is rather complex, disease can be avoided or reversed with early intense treatment by a simple change in diet. Cox et al. (2008) described the outcome for a 5-year-old girl with VLCAD deficiency that was first seen at 5 months of age with severe hypertrophic cardiomyopathy (Cox, et al., 2008). Molecular genetic analysis revealed two VLCAD mutations. The patient was placed on a low-fat diet supplemented

with medium-chain triglyceride oil and avoidance of fasting (Cox, et al., 2008). Over the course of a year, her ventricular hypertrophy resolved significantly (Cox, et al., 2008). The case study presented by Cox et al. (2008) expressed the importance of early clinical recognition of VLCAD deficiency because it is one of few directly treatable causes of cardiomyopathy in children (Cox, et al., 2008).

Three disease phenotypes associated with VLCADD have been documented. Severe infant onset is characterized by acute metabolic decompensation with hypoketotic hypoglycemia, dicarboxylic aciduria, liver dysfunction and cardiomyopathy. The patients who have survived their initial symptoms exhibit progressive cardiomyopathy and have a reported 75% mortality (Schiff, et al., 2013). The second form of the disease presents later in infancy or early childhood but has a milder phenotype that does not include cardiac involvement (Goetzman, et al., 2007). The third form presents itself in adolescents or adults and is dominated by muscle dysfunction, which is often induced by exercise. Andresen et al. (1999) examined the correlation between the phenotypes and the known VLCAD genotypes associated with the deficiency. They examined 58 different mutations in 55 unrelated individuals. The results of this study showed a clear relationship between the nature of the mutation and the severity of the disease (Andresen, et al., 1999). Patients that presented severe childhood phenotypes have mutations that resulted in no residual enzyme activity, whereas those that displayed the milder childhood and adult phenotype have mutations that may have resulted in residual enzyme activity (Andresen, et al., 1999).

The American College for Molecular Genetics (ACMG) has developed a uniform set of guidelines for newborn screening programs. Five fatty acid oxidation disorders were included in the core panel: medium chain acyl-CoA dehydrogenase deficiency (MCADD); very long chain

acyl-CoA dehydrogenase deficiency (VLCADD); long-chain L-3-OH acyl-CoA dehydrogenase deficiency (LCHADD); trifunctional protein deficiency (TFPD); carnitine uptake defect (CUDD) (Watson, et al., 2006). VLCADD is the second most common enzymatic deficiency that affects the fatty acid oxidation pathway, behind MCADD. MCADD has a higher prevalence of disease compared to VLCADD. Data collected from newborn screening programs suggested a VLCADD prevalence of 1:31,500 to 1:125,000 in Caucasians; whereas MCAD has a suggested prevalence of 1:4,900 to 1:17,000 (Olsen, et al., 2010) (Matern, et al., 2012). However, both MCAD and VLCAD were given high scores based on the ACMG selection criteria for newborn screening programs in part because of the significant health impact genetic conformation tests can yield. Early identification of affected individuals allows simple dietary treatments to be communicated to the parents and started before any significant fatty acid build up occurs in the infant.

Gene Structure and Mutations

VLCAD is encoded by the *ACADVL* gene (OMIM entry: MIM*609575)¹. It is the only gene in which mutations are known to cause VLCAD deficiency. The VLCAD enzyme also has the following aliases: ACAD6, LCACD, and ACADVL. The gene itself is fairly compact, consisting of 5.4 kilobases (kb) from the presumed transcription start site to poly (A) addition. It is located on the short arm of chromosome 17 at position 13.1 (17p13.1) and contains 20 exons ranging from 63-309 base pairs (bp) in length. Fifty-eight percent of the gene is composed of introns. The largest intron is 459 bp and the smallest is 71 bp. One unique aspect of the *ACADVL* gene is its high GC content. The exon and intron percent GC content are 58% and 61% respectively (Leslie, et al., 2011).

¹ <http://www.omim.org/entry/609575>

According to the Human Genome Mutation Database (HGMD)², there are 196 known mutations in *ACADVL*. The HGMD has described 116 of these and 80 have recently been reported in a study explaining gene scanning through high resolution melting (HRM) analysis (Olsen, et al., 2010). The nomenclature used to identify a mutation can be described as follows: “c.” stands for the coding DNA; the number corresponds to the nucleotide position; the first letter describes the homozygous wild-type DNA; the second letter describes the homozygous mutant DNA. One of the most common pathological alleles is c.848T>C where amino acid valine is substituted for alanine. The c.848T>C is observed in symptomatic compound heterozygotes and in homozygotes. It makes up about 20% of mutant alleles of the individuals detected by newborn screening. Other frequent mutations include c.779C>T and 830_832del, which are located in close proximity to one another on exon 9.

Current Testing Protocol

VLCADD is currently identified by newborn screening (NBS) of acylcarnitine profiles from plasma or dried blood spots with tandem mass spectrometry followed by molecular genetic testing of *ACADVL*. Tandem mass spectrometry, or MS/MS, uses two mass spectrometers in tandem to determine the molecular structure of analytes. For VLCADD identification, the MS/MS measures C14-C20 straight chain acyl carnitine esters, 3-hydroxy-acyl carnitine esters, and unsaturated acyl carnitine esters. This method is most sensitive during periods of metabolic stress, such as fasting. The C14:1 acylcarnitine is the principle metabolite used to identify VLCADD; however, it does not always discriminate between affected patients and carriers and healthy individuals. Schmyck et al. (2006) analyzed acylcarnitine levels in two patients on day

² The Human Gene Mutation Database: <http://www.hgmd.org/>

three of life. The study showed that during the catabolism on day 2 to 3 of life, all transporters and enzymes required for fatty acid beta-oxidation were induced, thereby normalizing the C14:1-carnitine levels in patients with mild VLCADD (Schymik, et al., 2006). Samples that screened positive for the presence of pathological acylcarnitine esters are confirmed through molecular genetic testing. These secondary tests include sequence analysis and deletion/duplication analysis. Sequence analysis, which is a PCR-based approach, involves sequencing all 20 exons and exon/intron boundaries of the gene. This approach has been shown to detect mutations in 85%-93% of individuals with VLCADD. Deletion/duplication analysis is performed if sequencing results did not identify a mutation. The methods used for deletion/duplication detection include quantitative PCR, long-range PCR, probe amplification, or targeted chromosomal microarray analysis (Leslie, et al., 2011).

High Resolution Melting (HRM) Analysis

The melting properties of DNA have assisted in the development of many clinical, genetic and forensic tests (Erali, et al., 2008). As the DNA double helix is heated, the strands separate in a process called denaturation or melting. For short PCR products, the melting occurs in one transition, whereas longer PCR products may melt in multiple stages, also known as melting domains (Erali, et al., 2010). The melting temperature (T_m) of the DNA is dependent on GC content, length and sequence composition, so PCR products can be distinguished by their melting curves (Ririe, et al., 1997). The T_m is defined as the temperature at which half of the duplexes are dissociated (Erali, et al., 2010). It is conventionally monitored by UV absorbance, which requires micrograms of DNA for high quality melting curves. Unlike UV absorbance, monitoring DNA melting with fluorescence is more sensitive and only requires nanograms of

DNA input. This technique is accomplished by incorporating fluorescent dyes into the PCR reaction.

In 1997, fluorescent DNA melting as a companion to real-time PCR was first introduced with the LightCycler instrument (Idaho Technology and Dr. Carl Wittwer's DNA Lab at the University of Utah) (Wittwer, 2010). The implementation of fluorescence-based DNA melting coupled with PCR required no handling, processing, or separation of the sample after amplification. Methods for both probe and amplicon melting were developed and incorporated into the real-time PCR instruments (Wittwer, 2010). Amplicon melting with SYBR Green I (Life Technologies, Inc.) became more popular than the probe based methods primarily because of cost and convenience of PCR product analysis after amplification (Wittwer, 2010). These saturating dyes are a new family of double-stranded DNA binding dyes that allow genotyping by melting without the use of a fluorescently-labeled probe. The dye is highly fluorescent when bound to double-stranded DNA, but it fluoresces poorly in the unbound state. After the target of interest has been amplified, the amplicon is gradually denatured by increasing the temperature in small increments. Initially, any double-stranded DNA that is present will show high levels of fluorescence, and as the temperature increases, the fluorescence will begin to decrease. Then, at a characteristic temperature, the fluorescence rapidly drops (**Figure 2A**). This reflects the melting of DNA into single strands.

The first real-time PCR instruments did not focus on the melting quality of the data produced. In 2000, the Wittwer DNA Lab initiated a project with Idaho Technology to build a high-resolution melting (HRM) instrument. In 2002, the HR-1 instrument was introduced. This instrument used very small sample volumes and capillary tubes instead of a well plate, and dyes

with higher saturation levels were used in the PCR chemistry, enabling HRM to progress (Wittwer, 2010). HRM analysis software packages are used to identify pre- and post-melt fluorescence intensity. The melting temperature (T_m) can be approximated by taking the negative first derivative ($-dF/dT$) of the melting curve (**Figure 2B**) (Reed, et al., 2007) (Erali, et al., 2008). These signals are automatically normalized to relative values, eliminating differences in background fluorescence (**Figure 2C**). The melting temperature shifts as well as the curve shape are used to identify possible variants. One form of this analysis is performed during gene scanning where the data are typically plotted as difference curves to better magnify the differences between the melting profiles of different samples (**Figure 2D**) (Reed, et al., 2007). Conventionally, gene scanning compares unknown samples to a “normal” sequence. Overall, HRM is being used to detect small nucleotide changes, especially for single nucleotide polymorphism (SNP).

There are two major applications of high resolution melting: targeted genotyping and gene scanning. Liew et al. (2007) describes two common methods for genotyping single nucleotide polymorphisms (SNPs): unlabeled oligonucleotides (probes) and amplicon melting. Unlabeled probes are designed to detect the mutation of interest without the added cost of being fluorescently tagged (Liew, et al., 2007). This method is similar to the conventional hybridization probes except that only one probe is needed and a saturating DNA dye, LC Green I (Idaho Technologies), is used instead of covalently attached fluorescent labels (Liew, et al., 2007). Unlabeled probe assays utilize an asymmetric PCR in which one PCR primer is added in excess of the other PCR primer. As a result, two melting peaks are produced: the melting of the double-stranded amplicon and the melting of the probe off of the single-stranded product derived

from asymmetric PCR (Dames, et al., 2007). Genotyping depends on the differences in the probe melting temperatures (T_m s) (Liew, et al., 2007). In contrast to amplicon melting, there is an added cost of an additional oligonucleotide for the intended PCR reaction.

A second method for genotyping SNPs is direct amplicon melting. Direct amplicon melting was initially developed for small amplicons (<50 bp) (Liew, et al., 2004). Shorter products allows for greater differentiation because T_m differences among genotypes increases as the size of the amplicon decreases (Liew, et al., 2004). This is especially advantageous in the detection of homozygous mutations because some homozygous SNPs have melting curves identical to that of the wild-type (Palais, et al., 2005). This method does not require probes for mutation detection. Only the two primers required for PCR are needed. Genotyping is accomplished by observed changes in the shape of the melting curves or detecting a difference in T_m . Heterozygotes are easily detected by shape changes using this method, but differentiating between two homozygotes can be difficult because some base changes do not confer large differences in T_m (Liew, et al., 2007). Homozygous genotypes of class 3 and class 4 single base variants, or “base pair neutral” variants, are difficult to distinguish by simple amplicon melting (Erali, et al., 2010). They comprise approximately 12% of human single base variants and have T_m differences around 0.25°C, whereas class 1 and class 2 homozygous variants have T_m differences around 1°C (Erali, et al., 2010). Palais et al. (2005) proposed a method to better enhance homozygote detection by mixing unknown samples with samples of a known genotype. This quantitative heteroduplex analytical approach differentiates between heterozygotes, homozygotes and wild-type DNA samples. If heteroduplexes are detected, then the samples mixed are of different genotype (Palais, et al., 2005).

Another application for HRM is gene scanning. Gene scanning is the search of unknown variations in PCR amplicons prior to sequencing (HRM, 2007). This detection method uses larger sequences in detection and thus is better at detecting differences related to the presence of heteroduplexes that distort the shape of the melting curve (Reed, et al., 2007). This change in shape is best observed when comparing the normalized melting curves of a homozygous standard to a heterozygous sample (Reed, et al., 2007). If one is looking for a mutation as a result of a single base change, the difference in temperature is small, so it is magnified by plotting the data as a difference curve (**Figure 2D**). Scanning is not ideal for identifying homozygous variants within a gene. As mentioned in the previous paragraph, homozygous detection can be enhanced by adding a known reference sample to samples with unknown genotypes (Palais, et al., 2005). If the known sample is wild-type, it will form a heteroduplex when added to homozygote samples. This newly formed heteroduplex will distort the shape of the melting curve, thereby identifying the presence of a homozygous mutation. Currently, many *ACADVL* SNPs are detected by conventional sequencing methods. In order to cover an entire gene sequence using the Sanger method, many reactions are performed, and then the data from these reactions must be edited together. Depending on the gene, this process could take days or weeks to complete. Wittwer et al. (2010) proposed the use of scanning as a screening method to identify mutations in large gene regions. Confirmation of such a mutation would be far less labor intensive and align with a conventional newborn hospital stay.

Olsen et al. (2010) developed a method for HRM analysis of the *ACADVL* gene using DNA extracted from newborn screening dried bloodspots. The samples were amplified on a Peltier Thermal Cycler (Bio-Rad Laboratories), and HRM was performed on the LightScanner

(Idaho Technologies). They tested the sensitivity and specificity of the assay by performing a blinded study with 183 samples from healthy controls and 146 samples from clinically affected VLCADD patients. All samples were correctly genotyped using HRM analysis. A similar method is proposed for the assay design described in this thesis; however our study utilizes multiple PCR chemistries in which I introduce a PCR protocol that is seven times faster than what was previously demonstrated by Olsen et al. (2010). I developed an assay that is a faster diagnostic approach for the detection of mutations in the *ACADVL* gene using high resolution melting analysis.

Figure 1. Fatty acid transport and beta-oxidation pathway.

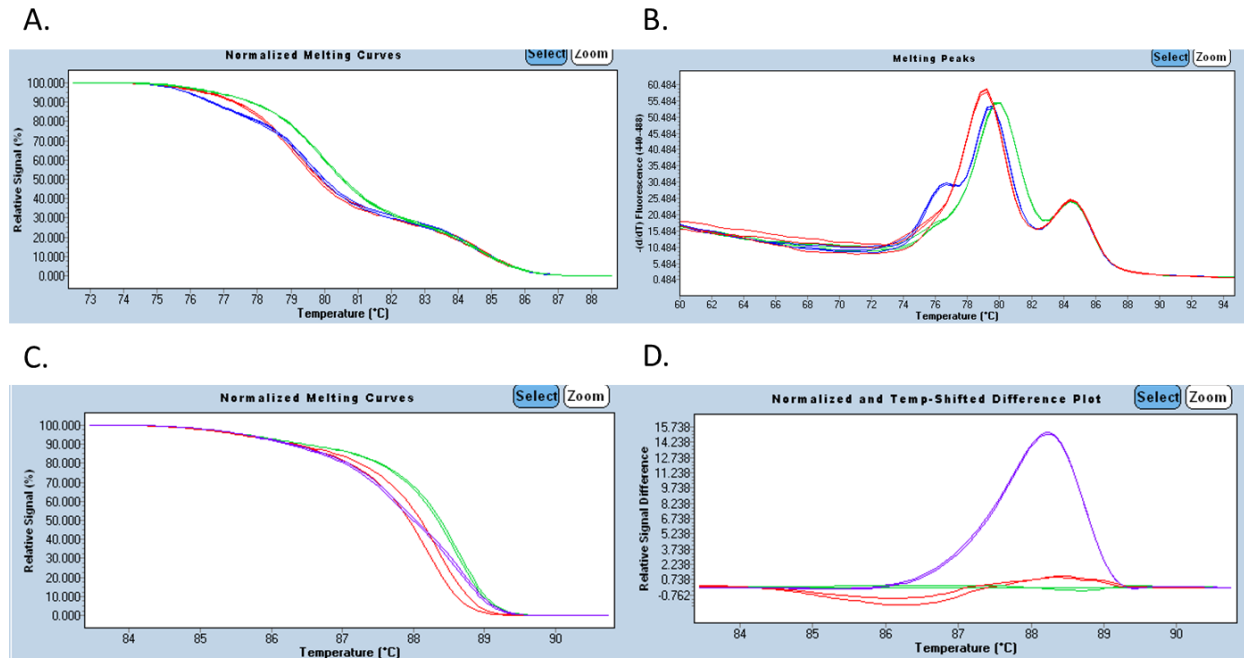

Figure 2. Two main applications of high resolution melting are genotyping and gene scanning. The genotyping results are depicted by the normalized melting curve (A) and derivative plot (B). Heterozygous (blue) and homozygous (red) mutants are distinguishable from the wild-type (green). The gene scanning results are depicted by the normalized melting curve (C) and difference plot (D). Heterozygous (purple) and homozygous (red) mutants are distinguishable from the wild-type (green).

CHAPTER II

MATERIALS AND METHODS

Primer Design

The primer design was performed by a senior scientist on the Research and Development team at Canon US Life Sciences, Inc. This section is in reference to the following technical report: *ACADVL Scanning Feasibility on the Light Cycler 480* (Benkhadra, Papazisi, & Huuskonen, 2013). The primer pairs were positioned on the intronic regions of the gene, so each PCR product (amplicon) corresponded to an entire exon.

VisualOMPTM software package (DNA Software Inc.) was used for primer design using ACADVL reference sequence with NCBI accession number NG_007975. For the two-step PCR conditions aiming at an annealing and extension temperature of 70°C, primer pairs were designed and selected based on the follow main criteria (Benkhadra, Papazisi, & Huuskonen, 2013):

- PCR chemistry: 50 mM NaCl, 2.96 mM MgCl₂, 2% DMSO, 1M Betaine, and pH=7.0 (pH is the only fixed condition in the VisualOMPTM software package).
- Binding kinetics and melting temperature (T_m) of the primers.
- The distance between the forward primer's 3' end and exon's 5' end (sense strand), as well as distance between the forward primer's 3' end and exon's complementary sequence 5' (anti-sense strand) were preferred to be ≥ 15 bp and ≤ 5 bp respectively.
- Amplicon length was preferred not to exceed ≤ 300 bp.
- Primers with minimal binding capacity between $\geq 90\%$ and $<100\%$ were accepted; however those with binding capacity between ≥ 95 and $<100\%$ were preferred.
- Primer pairs with $\Delta G \leq -2\text{kcal}$ were accepted, but not preferred.

Non-specific primer binding was investigated using the ThermoBlastTM software package (DNA Software Inc.) and PrimerBlast³, NCBI's online tool. Primer pairs that showed non-specific binding were omitted ($-4 < \Delta G < -2$) (SantaLucia Jr., 2007).

PCR Efficiency

Each set of primers was screened on the Light Cycler 480 (Roche Diagnostics, Indianapolis, IN) and the BioRad CFX (Bio-Rad, Hercules, CA). During the time period when this study was conducted, a major effort was carried out simultaneously to optimize the PCR chemistry to ultimately suit the prototype instrument that was being developed at CLS. Hence, three different PCR chemistries were used in this set of experiments: Takara Ex Taq Hot Start Polymerase (Clontech, Mountain View, CA) with 10X Canon US Life Sciences (CULS) buffer, Titanium KlenTaq DNA Polymerase (Clontech) with 2X CULS buffer pH 8.5, and Titanium KlenTaq DNA polymerase with AT Buffer. Each time the chemistry was changed, the experiments were repeated to ensure that PCR efficiency was not affected.

The first two chemistries listed (10X CULS buffer and 2X CULS buffer pH 8.5) were used in the initial primer screening experiments. Multiple primer pairs were designed for each assay, and this set of experiments established the best primer pair for each exon. Genomic DNA from cell line NA11254 and from NA09820 (Coriell Cell Repository, Camden, NJ) was used as the template. All PCR reaction mixtures contained 3 mM MgCl₂, 0.2% BSA, 1.6 mM dNTPs, 1 µM of each primer and 1X LC Green PlusTM (Idaho Technologies, Salt Lake City, UT) and 10 ng/µl of DNA in a final reaction volume of 10 µL. The 10X CULS buffer did not contain 1M Betaine or 2% DMSO, so these constituents were added separately to the master mix.

³ Primer Blast: <http://www.ncbi.nlm.nih.gov/tools/primer-blast/>

The PCR chemistry was changed from the CULS buffer system to the AT buffer system. The primer pairs selected for each assay were retested on the Light Cycler 480 in the AT Buffer. This is a three component system consisting of a DNA Dilution Buffer, Primer Master Mix, and DNA Master Mix. All PCR reaction mixtures contained 20 mM Tris-HCl pH 8.3, 30 mM KCl, 1M Betaine, 2% DMSO, 0.05% BSA, 4.5 mM MgCl₂, 0.04% Tween20, 1X Titanium Taq Polymerase (Clontech, Mountain View, CA), 1 µM primers, 9 ng/µl of genomic DNA (cell line NA11254), 1.5 mM dNTPs, and 1X LC Green PlusTM (Idaho Technologies, Salt Lake City, UT). The components were added in a 1:1:1 ratio in a final PCR reaction volume of 18 µl.

The performance of the primers was dependent on the PCR cycling conditions as well as the buffer system that was used. After the change to the AT Buffer system, re-optimization of the PCR cycling conditions was required for most of the assays. **Table 1** lists the cycling conditions selected in CULS buffer as well as the new conditions established with the AT buffer system.

The amplification plots shown in **Figure 3** represent three different scenarios: ideal amplification plot with the curves reaching plateau; acceptable amplification plot with high maximum fluorescence (relative fluorescence units or RFUs) levels; and very poor amplification with high crossing point (Cp) values and low fluorescence levels. These three scenarios were common during the cycling optimization process on the LightCycler 480. Primers for each assay were scored based on specific amplification criteria as well as the purity of the PCR product. Crossing point (Cp) values above 28 cycles were considered poor, and signal-to-noise (SNR) ratios greater than 2.5 were optimal.

The Caliper LabChip GX (Perkin Elmer, Waltham, MA) is a genetic analyzer that performs electrophoretic separation of samples on a microfluidic platform. It provides

information such as PCR product (amplicon) size, amplicon purity, and sample concentration. In this set of experiments, the purity of the target for chosen assays was greater than 95% (**Appendix Figure 4**). After carefully evaluating the data, the best performing pairs were chosen for genotyping.

Genotyping with Synthetic Constructs

Genomic DNA samples containing known mutations for the *ACADVL* were not readily available. One method to evaluate the feasibility of an assay is by designing synthetic constructs containing specifically selected mutations. The constructs behave similarly to genomic DNA in terms of PCR and melting properties. In this study, we designed a series of synthetic constructs for all 20 exons of the *ACADVL* (Gene Oracle, Mountain View, CA). The constructs were designed to contain two neighboring exons per construct, with an intervening intronic sequence (~200 bp) in between. This helped reduce the total number of constructs and processing steps. Upon receipt from Gene Oracle, the constructs were diluted 1:10 in TE buffer pH 7.0 (1 µl construct in 9 µl TE buffer) (Ambion, Grand Island, NY). The concentration of each construct was measured in triplicate on the Nanodrop 2000 (Thermo Fisher Scientific, Rockville, MD), averaged and recorded. The constructs were further diluted to the following working concentrations: 100 pg/µl, 5 pg/µl and 0.067 pg/µl. A list of the *ACADVL* synthetic constructs can be found in **Table 2**.

The following experiments were performed for exons 1, 3-17, 19 and 20. Wild-type (pWT), homozygote (pHM), and heterozygote (pHT) construct DNA were used to genotype on the Light Cycler 480. Heterozygotic construct was made by mixing equal quantities of the wild-type and homozygote plasmid DNA (pDNA) together. Genomic DNA extracted from cell line

NA11254 and NA09820 (Coriell Cell Repositories, Camden, NJ) were used to examine initial performance with the genomic DNA. The final template concentration of 5 copies/nl was matched for genomic DNA and construct DNA in the 10 μ l reaction mixture on the Light Cycler 480.

The PCR chemistry used was 1X Titanium KlenTaq DNA polymerase (Clontech, Mountain View, CA) with 2X CULS buffer pH 8.5. All PCR reaction mixtures contained 3mM $MgCl_2$, 0.2% BSA, 1.6 mM dNTPs, 1 μ M of each primer, 1X LC Green PlusTM (Idaho Technologies, Salt Lake City, UT) in a final reaction volume of 10 μ L. PCR was performed with a 2-minute hot-start at 95°C. The cycling conditions, however, varied with each assay. The results were analyzed on the Light Cycler 480 Gene Scanning software. Similar to the PCR efficiency tests, the best cycling conditions were chosen based on C_p values, signal-to-noise ratio (SNR), and amplification curve fluorescence level.

The PCR chemistry used in the genotyping experiment for exon 2 was Titanium KlenTaq DNA polymerase with AT Buffer. Wild-type, homozygote, and heterozygote construct DNA were used to genotype on the Light Cycler 480 (Roche Diagnostics). Heterozygotic construct was made by mixing equal quantities of the wild-type and homozygote DNA together. The PCR reaction mixtures contained 20 mM Tris-HCl pH 8.3, 30 mM KCl, 1M betaine, 2% DMSO, 0.05% BSA, 4.5 mM $MgCl_2$, 0.04% Tween20, 1X Titanium Taq Polymerase, 1 μ M primers, 9 ng/ μ l of genomic DNA (cell line NA11254) or 0.4 pg/ μ l of plasmid DNA, 1.5 mM dNTPs, and 1X LC Green PlusTM (Idaho Technologies). The final PCR reaction volume was 18 μ l. The results were analyzed on the Light Cycler 480 Gene Scanning software.

Blinded Study using Genomic DNA

In this study, a sample of 30 randomly selected genomic DNAs readily available in the laboratory were chosen. **Table 3** lists the cell lines and the corresponding number used to identify each DNA sample. The genotypes of these samples were unknown for the *ACADVL* gene. Each exon was tested with the 30 samples, and wild-type, homozygote, and heterozygote synthetic constructs were used as controls. The 3-component AT buffer system was used in this set of experiments. All PCR reaction mixtures contained 20 mM Tris-HCl pH 8.3, 30 mM KCl, 1M Betaine, 2% DMSO, 0.05% BSA, 4.5 mM MgCl₂, 0.04% Tween20, 1X Titanium Taq Polymerase, 1 uM primers, 9 ng/μl of genomic DNA or 0.4 pg/μl of plasmid DNA, 1.5 mM dNTPs, and 1X LC Green PlusTM (Idaho Technologies, Salt Lake City, UT). The final PCR reaction volume was 18 μl. The genomic DNA samples as well as the synthetic constructs were run in duplicate on a 96-well plate array, and PCR and HRM were carried out on the Light Cycler 480. The HRM data was analyzed with the Light Cycler 480 Gene Scanning software package.

Sequencing Protocol

The samples selected for sequencing were chosen based on the difference in their melting pattern compared to the melting pattern of the wild-type plasmid DNA. Once selected, the concentrations of each were determined by running the samples on the Caliper Lab Chip GX genetic analyzer (Perkin Elmer, Waltham, MA). The final reaction volume required by the Caliper GX for a 96 well plate set-up is 40 μl. In order to achieve this volume, 10 μl of sample was added to 30 μl of nuclease-free water (Ambion) and plated on a BioRad hard-shell 96 well plate array. The concentrations ranged from 9 ng/μl-120 ng/μl, which was equal to or greater

than the recommended concentration for sequencing (5 ng/μl-20 ng/μl). The PCR primers, both forward and reverse, were diluted in nuclease-free water to 5 μM. MacroGen (Rockville, MD) performed the sample purification and sequencing experiments. The results were analyzed with CodonCode Aligner software version 3.7.1 (CodonCode Corporation, Centerville, MA).

The cell lines were purchased from Coriell Cell Repositories (Camden, NJ), and the expansion and extraction of the DNA were performed by Texcell (Frederick, MD).

CHAPTER III

RESULTS

PCR Efficiency

Three different PCR chemistries were used in this study; however, the initial primer screening experiments were performed in the following buffer systems: Takara Ex Taq Hot Start Polymerase (Clontech) with 10X CULS buffer and Titanium KlenTaq DNA Polymerase (Clontech) with 2X CULS buffer pH 8.5. Once these experiments were complete, the primers were evaluated based on the following criteria: PCR C_p value, RFU of the amplification curve, and Caliper GX data. Samples below 95% purity were not selected for genotyping. Generally, no-template control (NTC) amplification was associated with the lower purity of the product, indicating the possibility of non-specific product and/or primer-dimer formation. **Table 4** contains a summary of the original amplification data for each primer pair selected for genotyping experiments on the Light Cycler 480.

When the PCR chemistry was changed, the primers were reevaluated in the AT buffer with Titanium KlenTaq DNA polymerase on the Light Cycler 480. Different primer pairs for exon 6 and exon 13 were used: 224/177 and 559/560, respectively. Each yielded a more efficient PCR and purer product compared to the previous primer pairs used for exon 6 and exon 13. The previously established cycling conditions required optimization in the AT buffer system. For

most of the assays, the annealing temperature and/or cycling times were changed. The new conditions were chosen based on the following criteria: Cp values, maximum fluorescence of the amplification curve, and Caliper GX data. **Table 5** contains a summary of the amplification results for each primer pair. The design characteristics for each primer pair that was chosen for genotyping are listed in **Table 6**.

Genotyping with Synthetic Constructs

Table 7 summarizes data from the PCR experiments using construct DNA in the CULS buffer. The PCR efficiency was evaluated based on the following criteria: Cp values, SNR, Caliper GX data, and gene scanning results. The Caliper GX provided the purity of the sample (wild-type target amplicons were >96% pure) and size of the target (**Appendix Figure 5**). The purity of the heterozygous samples was <95% for some of the assays tested. In these instances, there was a secondary product present that was similar in size to the target amplicon. An example from exon 17 is shown in **Appendix Figure 6**. The Light Cycler 480 gene scanning software was used to analyze the genotyping results from this set of experiments. Based on the results derived from the Light Cycler 480 melting analysis software, all construct heterozygotes were detectable. Homozygote variants were detectable in 12 out of 19 assays as well (Exons 1, 2, 5, 6, 8, 11, 12, 13, 15, 17, 19, and 20). **Table 8** is a summary of the genotyping results from this set of experiments.

Blinded study using genomic DNA

In the experiments performed with the 30 different genomic DNA samples, a true wild-type genomic DNA was not known for the *ACADVL*. The data were analyzed with the Roche LightCycler 480 Gene Scanning software package. Wild-type plasmid DNA was selected as the baseline for the analysis. Samples with a relative fluorescence difference of ± 1.0 or greater from the normalized baseline (plasmid wild-type) were selected as candidates for sequencing. Samples within ± 1.0 units from the baseline were also selected for sequencing. This was a very conservative selection since we had no prior experience on what magnitude of difference to expect from potential heterozygous samples. In a real clinical setting, the cut-off value would have been predetermined by using known samples with mutations, as well as to determine the sensitivity and specificity of a particular assay.

The difference plot for exon 16 is depicted in **Figure 7**. There are five distinct melting patterns. Samples from each group were selected for sequencing. The same selection criteria were used for the other assays (**Appendix Figures 8-25**). After careful analysis of each assays' melting curves, 85 samples were chosen for sequencing. **Table 9** contains a list of all DNA samples sent for sequencing and the confirmed genotypes.

Sequencing Results

A total of 85 samples were sequenced bi-directionally by MacroGen (Rockville, MD) using automated Sanger sequencing technology. Upon receipt of the sequencing results, the files were uploaded into sequence alignment software, Codon Code Aligner. The amplicon sequences were downloaded from NCBI BLAST and uploaded into Codon Code Aligner as well. The software is capable of aligning the forward and reverse strands to the amplicon reference sequence. If a mutation is present, the nucleotide is not defined. It is typically given an arbitrary “N” value.

A total of 21 of the 85 samples sent for sequencing contained a mutation. From the 21 mutated samples, 7 different mutations were identified with the Codon Code Aligner software. The location and frequency of each mutation are listed in **Table 10**. Alamut, a sequence alignment and annotation software, was used to identify the types of mutations that were found and where they were located on the gene. Alamut confirmed that each mutation discovered was a single nucleotide polymorphism (SNP). The frequency of each mutation in nature, as reported by NCBI’s dbSNP database, was very similar to the frequency calculated in this study with a sample size of 30 (**Table 10**). The low number of mutations detected in these samples is aligned with our prediction that the low cut-off value in a difference plot (see description above) would result in most samples showing no mutations.

Table 8. ACADVL Scanning assay genotyping results from the Light Cycler 480. Exon 2 is the only assay evaluated in the AT buffer for this data set. The cells highlighted in yellow represent instances where the software clustered the construct wild-type and construct homozygote together even though the patterns generated by the difference plot were different. If there was variability among replicates, the cell was highlighted yellow. If the homozygote variant and its wild-type were indistinguishable, the cell is highlighted red. For clear genotyping results, the cell is highlighted green.

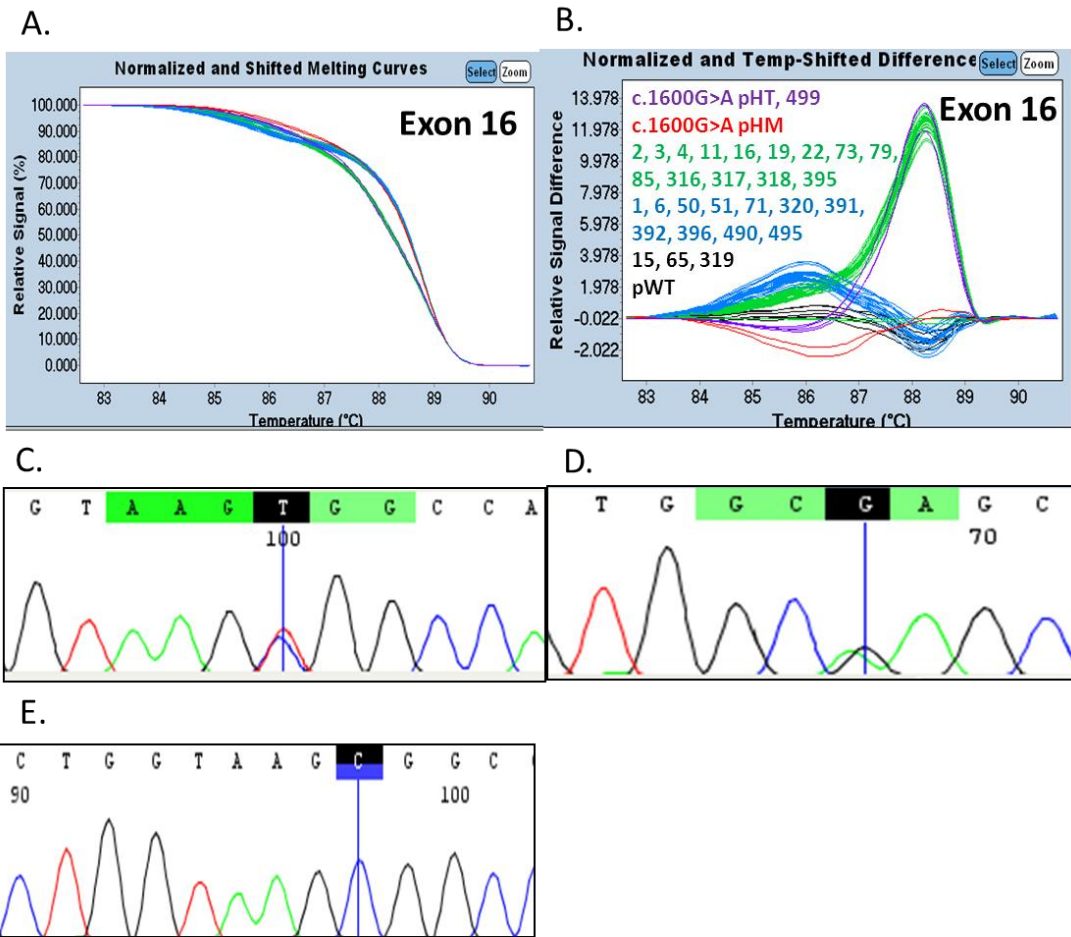

Figure 7. Summary of ACADVL exon 16 HRM scanning and sequencing results.

Normalized HRM curve (A), difference plot (B) and sequencing results (C-E) from Exon 16 blinded experiments with 30 randomly selected genomic DNA samples from. The difference plot shows 5 distinct groups: blue, green, purple, red and black. The sample colors were manually assigned. The sequencing results (C) confirmed the presence of a heterozygous mutation: c.1605+6T>C. The sequencing results (D) confirmed the presence of a heterozygous mutation: c.1600G>A. The sequencing results (E) confirmed the presence of a homozygous mutation: c.1605+6T>C.

Table 10. The average frequency of each mutation as reported by the dbSNP or ESP database and the mutation frequency calculated from the blinded study. The frequencies reported by the dbSNP and ESP databases represent the average heterozygosity.

*This was the only homozygous mutation detected.

CHAPTER IV

DISCUSSION

The focus of this thesis was on the development of the *ACADVL* gene scanning assay using a two-step PCR coupled with high resolution melting (HRM) analysis. We were able to genotype 19 exons on the Light Cycler 480 using synthetic constructs and HRM as the analytical method of detection. All heterozygote and 11 out of 18 homozygote mutations were detectable in the CULS buffer system for the following exons: 1, 5, 6, 8, 11, 12, 13, 15, 17, 19, and 20. When the PCR chemistry changed to the AT buffer, all heterozygote mutations were once again detectable, but we were only able to detect 9 of the 19 homozygote plasmid DNA mutants (Exons 2, 5, 6, 8, 9, 10, 11, 15, and 16). The inability to detect all homozygous mutations in a scanning assay is a known phenomenon. Palais et al. (2005) explains an alternative approach to homozygote detection by quantitative heteroduplex analysis using high resolution melting. In his study, he added a known wild-type sample to samples with all three genotypes. Heteroduplexes formed when wild-type DNA was added to homozygous and heterozygous mutants. The number of heteroduplexes that formed depended on the genotype of the unknown sample and the fraction of wild-type DNA added (Palais, et al., 2005). The difference between the melting curve of the wild-type and the melting curve of the mutant was enhanced when wild-type DNA was added to homozygous samples. The opposite was true when wild-type DNA was added to heterozygous samples. According to Olsen et al. (2010), since homozygous detection depends on small differences in T_m between alternative genotypes, it is especially sensitive to variations in sample chemistry (Olsen, et al., 2010). This could explain the decrease in homozygote detection we saw when the PCR chemistry changed to the AT buffer. Unfortunately, we were unable to produce

successful PCR results for exon 18. Numerous primer pairs were designed and tested on the Light Cycler 480, but we were still unable to optimize this assay. Even though we were unable to deduce the reason behind the inefficiency of the exon 18 assay, the preliminary data revealed that the primers were amplifying other unknown targets.

After PCR efficiency was established, we performed a blinded study with 30 different genomic DNA samples that were selected at random. Since a true wild-type genomic DNA was not known for the *ACADVL* gene, synthetic constructs were used as controls. Samples with a relative fluorescence difference of ± 1.0 or greater were sent for sequencing. This was a very conservative cut-off value, and we knew to expect many wild-type sequences returned. We selected samples from each cluster, including those that appeared to be wild-type, and sent them to MacroGen for purification and sequencing. Sequencing results proved that the selection criteria we chose was indeed appropriate. Samples with relative fluorescence difference values within ± 1.0 range were wild-type whereas those with relative fluorescence difference values outside these boundaries were found to harbor mutations (**Table 9**). A total of seven mutations were detected with HRM, and these samples were confirmed by DNA sequencing (**Table 10**). All seven mutations were non-pathogenic single nucleotide polymorphisms (SNPs) that had been previously reported in either the Single Nucleotide Polymorphism database (dbSNP) or the Exome Sequencing Project database (ESP). The heterozygous mutation for exon 2, c.128G>A, is a non-synonymous substitution that changes amino acid glycine to a glutamic acid residue. Four of the mutations (homozygous and heterozygous c.1605+11T>C, heterozygous c.623-8C>T and heterozygous c.1532+11G>A) are non-coding substitutions that do not affect the amino acid sequence. The heterozygous mutation found at position c.1600G>A on exon 16 is a non-

synonymous substitution that changes amino acid glutamic acid to a lysine residue.

Heterozygous mutation c.663C>T is synonymous base substitution that does not alter the amino acid produced. The reported frequencies for each of these mutations were compared to the frequencies calculated based on our set of experiments (**Table 10**). The calculated frequencies were very similar to the expected frequency for each mutation as reported in the dbSNP or ESP databases.

HRM is the only scanning method that does not require physical processing or separation steps after amplification. The popularity of this analytical method is growing rapidly because of its simplicity (Erali & Wittwer, 2010). By removing the need for sample transfer, the risk of post-PCR manipulation and contamination is significantly reduced. Due to its speed and accuracy, this method could also substitute current metabolic testing. The data presented in this thesis supports the development of 19 out of 20 *ACADVL* scanning assays on the Light Cycler 480 and the sensitivity of the HRM technique for mutation detection within this gene. To bring this assay to clinical implementation, the following steps would be required: re-design, homozygote detection, clinical samples and clinical trials.

High resolution melting for gene scanning relies heavily on PCR quality, so optimization is critical. The current assay design outlined in this thesis requires different PCR cycling conditions for each exon. To move this assay towards clinical implementation, we would need further optimization of the PCR protocol is needed. Efficient PCR results were not obtained for exon 18. The primers require re-design so the *ACADVL* scanning assay encompasses all 20 exons.

Gene scanning relies heavily on detecting heterozygous mutants by shape differences in the melting curves (Erali & Wittwer, 2010). Since homozygous variants rely on temperature differences (T_m), it is difficult to observe these differences through gene scanning. Homozygous variants are best detected by mixing a normal and unknown DNA samples together so any homozygotes in the unknown will form heteroduplexes (Erali & Wittwer, 2010). This would improve our ability to detect homozygous variants in the *ACADVL*.

In this thesis, I demonstrated the feasibility of the *VLCAD* scanning assay using a fast PCR protocol and HRM analysis of different mutations in the gene. I successfully optimized the assay in multiple PCR chemistries and demonstrated that it could be transferred to a microfluidic platform. In conclusion, HRM proved to be a fast and accurate analytical tool available for molecular diagnostics. The method introduced in this study can potentially be utilized for molecular genetic testing of any inherited metabolic disorder.

CHAPTER V

APPENDIX

Figure 4. Two examples of Caliper GX-generated electropherograms pertaining to the PCR products for *ACADVL* exon 7. Genomic DNA was used as the template in both cases. Shown is a lower molecular weight marker (LM) and upper molecular weight marker (UM) in each image. The size of each amplicon is depicted in each graph as well. Electropherogram (A) is a Caliper GX image of primer pair 272/425. The larger peaks (354 bp and 369 bp) represent secondary products formed during amplification. Electropherogram (B) is a Caliper GX image of primer pair 3352/328. Only one band of the appropriate size (98% purity) was present in each well. This primer pair was chosen for genotyping.

Figure 5. Derivative plot pertaining to exon 16 amplicon using pDNA as template (A), and Caliper GX electropherograms for wild-type amplicon (B) and NTCs (C). Shown is a lower molecular weight marker (LM) and upper molecular weight marker (UM) in each electropherogram. The amplicon peak (B) was the appropriate size for exon 16 (156 bp), with a purity >96%. The NTC electropherogram (C) does not show any peaks between the lower and upper molecular weight markers. This indicates that no secondary products formed during amplification of exon 16.

Figure 6. Derivative plot pertaining to exon 17 amplicon using pDNA as template (A), and Caliper GX electropherograms for heterozygote amplicon (B) and NTCs (C). There is a lower molecular weight marker (LM) and upper molecular weight marker (UM) in each electropherogram. Two PCR products of similar size are present in the heterozygote amplicon (B). Smaller peaks are present in the NTCs (C) that do not represent the desired product. The peaks could be a result of left over primers from the PCR reaction.

Figure 8. Summary of *ACADVL* exon 1 HRM scanning results. Normalized HRM curve (A) and difference plot (B) for Exon 1 blinded experiments. The difference plot shows 2 distinct groups (blue and red). The sample colors were provided by the Light Cycler 480 Gene Scanning software.

Figure 9. Summary of *ACADVL* exon 2 HRM scanning and sequencing results. Normalized HRM curve (A) and difference plot (B) and sequencing results (C) for Exon 2 blinded experiments with 30 randomly selected genomic DNA samples from. The difference plot shows 4 distinct groups: green, red purple, and blue. Sequencing results from MacroGen show the presence of a heterozygote mutation: c.128A>G.

Figure 10. Summary of *ACADVL* exon 3 HRM scanning results. Normalized HRM curve (A) and difference plot (B) of Exon 3 blinded experiments with 30 randomly selected genomic DNA samples. The difference plot shows 2 distinct groups: blue and red. The sample colors were assigned by Light Cycler 480 Gene Scanning software.

Figure 11. Summary of *ACADVL* exon 4 HRM scanning results. Normalized HRM curve (A) and difference plot (B) of Exon 4 blinded experiments with 30 randomly selected genomic DNA samples. The difference plot shows 2 distinct groups: blue and red. The sample colors were assigned by Light Cycler 480 Gene Scanning software.

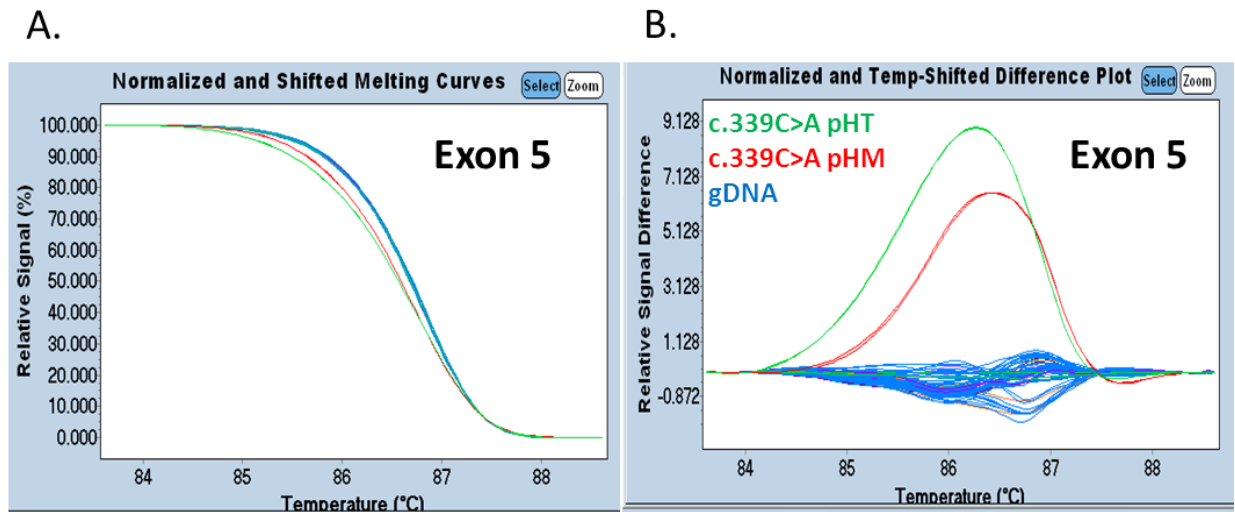

Figure 12. Summary of *ACADVL* exon 5 HRM scanning results. Normalized HRM curve (A) and difference plot (B) of Exon 5 blinded experiments with 30 randomly selected genomic DNA samples. The difference plot shows 3 distinct groups: blue, red, and green. The sample colors were manually assigned.

Figure 13. Summary of *ACADVL* exon 6 HRM scanning results. Normalized HRM curve (A) and difference plot (B) of Exon 6 blinded experiments with 30 randomly selected genomic DNA samples. The difference plot shows 3 distinct groups: blue, red, and green. The sample colors were manually assigned.

Figure 14. Summary of *ACADVL* exon 7 HRM scanning results. Normalized HRM curve (A) and difference plot (B) of Exon 7 blinded experiments with 30 randomly selected genomic DNA samples. The difference plot shows 2 distinct groups: blue and red. The sample colors were assigned by Light Cycler 480 Gene Scanning software.

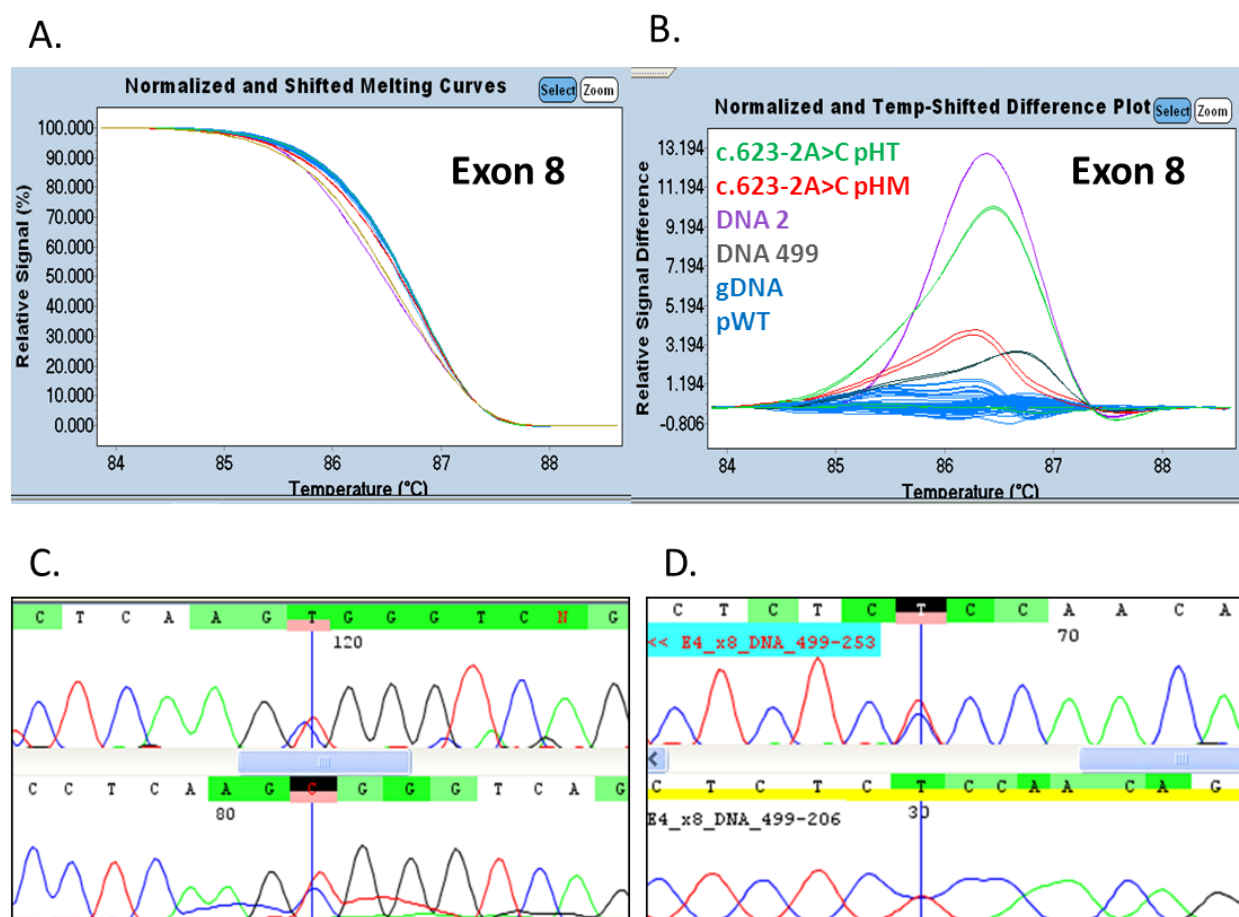

Figure 15. Summary of ACADVL exon 8 HRM scanning and sequencing results.

Normalized HRM curve (A) and difference plot (B) and sequencing results (C), (D) of Exon 8 blinded experiments with 30 randomly selected genomic DNA samples. The difference plot shows 4 distinct groups: blue, red, green, purple and black. The sample colors were manually assigned. The sequencing results (C) confirmed the presence of a heterozygous mutation: c.663C>T. The sequencing results (D) confirmed the presence of a heterozygous mutation: c.623-8C>T.

Figure 16. Summary of *ACADVL* exon 9 HRM scanning results. Normalized HRM curve (A) and difference plot (B) of Exon 9 blinded experiments with 30 randomly selected genomic DNA samples. The difference plot shows 2 distinct groups: blue and red. The sample colors were manually assigned.

Figure 17. Summary of *ACADVL* exon 10 HRM scanning results. Normalized HRM curve (A) and difference plot (B) of Exon 10 blinded experiments with 30 randomly selected genomic DNA samples. The difference plot shows 2 distinct groups: blue and red. The sample colors were manually assigned.

Figure 18. Summary of *ACADVL* exon 11 HRM scanning results. Normalized HRM curve (A) and difference plot (B) of exon 11 blinded experiments with 30 randomly selected genomic DNA samples. The difference plot shows 3 distinct groups: blue, red, and green. The sample colors were manually assigned.

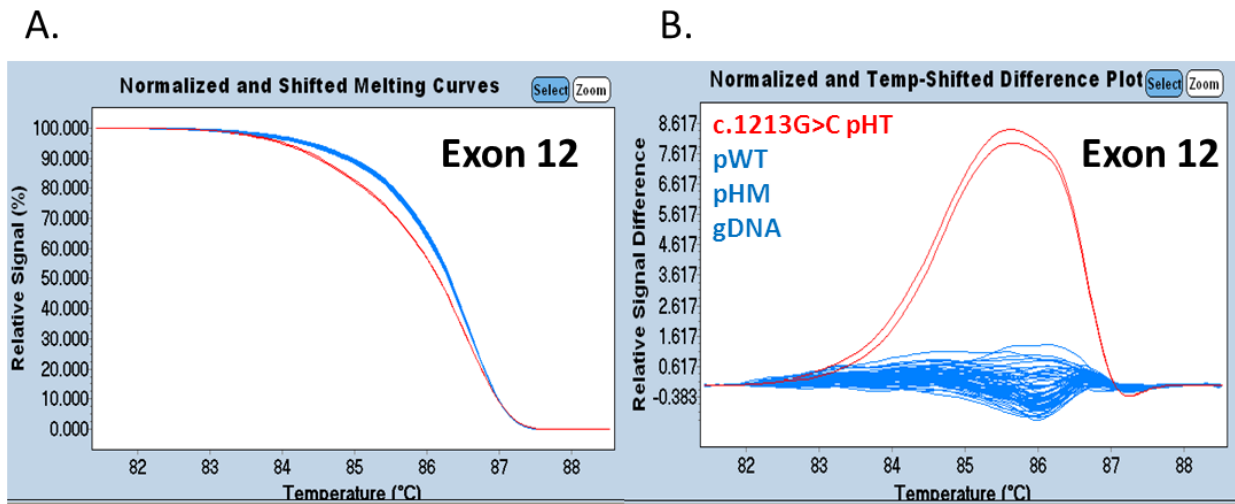

Figure 19. Summary of *ACADVL* exon 12 HRM scanning results. Normalized HRM curve (A) and difference plot (B) of exon 12 blinded experiments with 30 randomly selected genomic DNA samples. The difference plot shows 2 distinct groups: blue and red. The sample colors were assigned by Light Cycler 480 Gene Scanning software.

Figure 20. Summary of *ACADVL* exon 13 HRM scanning results. Normalized HRM curve (A) and difference plot (B) of exon 13 blinded experiments with 30 randomly selected genomic DNA samples. The difference plot shows 2 distinct groups: blue and red. The sample colors were assigned by Light Cycler 480 Gene Scanning software.

Figure 21. Summary of *ACADVL* exon 14 HRM scanning results. Normalized HRM curve (A) and difference plot (B) of exon 14 blinded experiments with 30 randomly selected genomic DNA samples. The difference plot shows 2 distinct groups: blue and red. The sample colors were assigned by Light Cycler 480 Gene Scanning software.

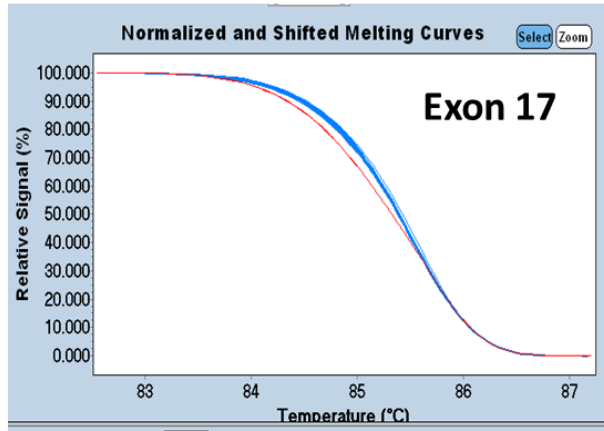

Figure 22. Summary of *ACADVL* exon 15 HRM scanning and sequencing results.

Normalized HRM curve (A), difference plot (B) and sequencing results (C) from Exon 15 blinded experiments with 30 randomly selected genomic DNA samples. The difference plot shows 4 distinct groups: blue, red, green, and purple. The sample colors were manually assigned. The sequencing results (C) confirmed the presence of a heterozygous mutation: c.1532+11G>A.

CURRICULUM VITAE

Education

Master of Science in Forensic Science
Towson University

May 2014
Towson, MD

Bachelor of Science in Biochemistry, Minor in Chemistry
Virginia Polytechnic Institute and State University (Virginia Tech)

December 2010
Blacksburg, VA

Experience**Associate Scientist**

Canon U.S. Life Sciences, Rockville, MD

March 2011-Present

- Designed PCR experiments for the *ACADVL* gene scanning assay.
- Performed DNA extractions from bacteria and blood using the Qiagen Qiacube and the Roche MagnaPure Compact instruments.
- Created and maintained a monthly budget for the Assay Development department.
- Trained personnel on proper lab safety.
- Wrote technical reports on projects completed.
- Wrote standard operating procedures.
- Assembled components for our prototype PCR and high resolution melting instrument.

Undergraduate Researcher

Biochemistry Department, Virginia Tech

September 2009 –May 2010

- Conducted research on *Arabidopsis* plants by varying environmental conditions and comparing wild-types and mutant forms.
- Performed experiments in which the effects of auxin, a plant growth hormone, were studied.
- Presented the research conducted to the lab in a power point presentation.

Laboratory Assistant

National Institute of Health, Bethesda MD

May – August 2007

- Successfully sub-cloned human Vps34 (a protein kinase) into a mammalian vector
- Transfected Vps34 into a cancer cell line in order to study its effects on vesicular trafficking within these cells.
- Well-trained in PCR procedures.

Relevant Training

- Blood Borne Pathogen
- Hazardous Communication
- First aid and fire safety
