**Abstract**

Aerosols emitted from biomass burning in South American tropical forests have been a concern in the last decades. On August 19<sup>th</sup>, 2019 darkened precipitation was observed over the metropolitan area of São Paulo (MASP), in an unprecedented event termed “black rain”, after intense biomass burning episodes in the South American hinterland. Satellite imagery, back trajectory analyses, and meteorological reports showed air masses transporting thick plumes of biomass burning aerosols originated in part from the Amazon Basin and Bolivia. Rainwater samples were collected in different sites of the metropolitan area, during and after the “black rain” event, and both physically and chemically characterized to assess the possible influence of biomass burning aerosols in the event. The collected samples in the “black rain” event presented high turbidity (above 70 NTU), and biomass burning organic tracers (levoglucosan, mannosan, and galactosan) were observed in higher concentrations in the “black rain” samples than in control ones (e.g. average

levoglucosan of  $0.33 \mu\text{g mL}^{-1}$ , compared to  $0.02 \mu\text{g mL}^{-1}$  after the event), with deposition fluxes more than three times higher during the event ( $1.04 \text{ mg m}^{-2}$  and  $0.31 \text{ mg m}^{-2}$ , respectively). The detection of glucose, xylose, and mannose, after hydrolysis of the solid material present in the “black rain” samples, strongly suggested the presence of plant cell wall material derived from the partial combustion of wood and grass matter. Total polycyclic aromatic hydrocarbons (PAHs) concentrations were, in general, higher during the event than in post-event control samples collected in the MASP (on average, almost 15 times higher than after the event), with a higher deposition flux ( $5.1$  and  $2.7 \text{ mg m}^{-2}$ , respectively). Overall, there are strong pieces of evidence that the long-range transport of smoke produced in South American forest fires was connected to the precipitation of darkened rainwater over the Metropolitan Area of São Paulo.

**Keywords:** Rainwater; biomass burning; Amazon; monosaccharides; polycyclic aromatic hydrocarbons

50   **Highlights**

- 51       •   Darkened precipitation was associated with smoke transport in São Paulo, Brazil.
- 52       •   Intense fire episodes were observed in the Amazon deforestation arch and Bolivia.
- 53       •   Satellite images and back trajectories revealed biomass burning aerosols transport.
- 54       •   Monosaccharides and retene in the rain samples confirmed biomass burning
- 55       influence.

## 1. Introduction

Particulate matter (PM) emitted from biomass burning in Brazilian forests has attracted attention in the last decades. The emission of PM can influence the radiation balance and act as cloud condensation nuclei (CCN), modifying cloud properties (Andreae et al., 2004; de Oliveira Alves et al., 2015, 2014; Koren et al., 2004; Schkolnik et al., 2005; Sena et al., 2013). Precipitation acts as a sink, carrying out of the troposphere dissolved airborne organic carbon and ionic species, which can be emitted by both anthropogenic and natural sources (Altieri et al., 2008; Avery et al., 2006; Mead et al., 2013; Mullaugh et al., 2014; Vieira-Filho et al., 2013).

Most biomass burning emissions happen in tropical areas during dry periods and can be a dominant source of particulate matter, an essential climatic driver (Seinfeld and Pandis, 2006). In the Brazilian dry season, there is an increase in the emission of aerosols from biomass burning in the *Cerrado* (savanna) and the Amazon regions (de Oliveira Alves et al., 2015; Santos, 2014). Efforts have been made to ban sugarcane burning in the State of São Paulo and other places in the Central-South region of Brazil in the last decade and they were much reduced by 2017 (Andrade et al., 2017; de Almeida Silva et al., 2020; Pereira et al., 2019). The Amazon represents approximately half of the remaining tropical forests on the planet, corresponding to 62 % of Brazilian territory (Malhi et al., 2008). Most of the forest fires in the Brazilian Amazon are located in an area of approximately 500,000 km<sup>2</sup>, known as the deforestation arc, and are associated with land-clearing practices to give place to pastures and crops (Artaxo et al., 2013; de Oliveira Alves et al., 2015).

Previous studies have found that the emissions from biomass burning in the Amazon dry season may cause adverse effects to human health of the local exposed

93 population; the particulate matter was observed to be both mutagenic and carcinogenic,  
94 with the potential risk of DNA damage, mutation, and cancer (de Oliveira Alves et al.,  
95 2014; de Oliveira Galvão et al., 2018). However, these biomass burning aerosols are lifted  
96 from the boundary layer into the free troposphere by clouds and pyro-cumulus clouds  
97 (Andreae et al., 2004; Darbyshire et al., 2019), from where they can be transported by  
98 winds for thousands of kilometers. Given the spatial scale of this transport, satellites are the  
99 most useful monitoring tool in South America (Edwards et al., 2006) and elsewhere  
100 (Duncan et al., 2003; Zhu et al., 2016). As a consequence of the long-range transport, these  
101 biomass burning aerosols can also affect the air quality in remote urban sites (Pereira et al.,  
102 2017a, 2017b; Vasconcellos et al., 2011).

103 Polycyclic aromatic hydrocarbons (PAHs) are important particulate organic  
104 compounds mainly emitted by anthropogenic sources (among them, biomass burning), and  
105 are frequently studied due to their carcinogenic properties (Pereira et al., 2017b; Ravindra  
106 et al., 2008). Because the burning of biomass is often incomplete, polysaccharides derived  
107 from plant biomass (e.g. cell wall components such as cellulose, xylans, and mannans) can  
108 be found in the particulate matter. The detection of such polymers can be done by  
109 measuring the levels of monosaccharides in atmospheric samples after the hydrolysis  
110 procedure. These findings can bring information about the transport of biological material  
111 and biomass burning aerosols emitted from remote places (Fu et al., 2012; Simoneit et al.,  
112 2004). The presence of sugar polymers in the biomass burning related aerosol increases its  
113 hygroscopicity, and influences cloud albedo and cloud formation, possibly affecting climate  
114 (Mullaugh et al., 2014; Russell et al., 2009).

115 Particulate matter can be transported by air masses and taken to the surface by  
116 raindrops and other forms of precipitation by the so-called rain-out and wash-out processes

(Cousins et al., 1999; Seinfeld, 2004). On August 19<sup>th</sup>, 2019, a unique phenomenon occurred over a significant extension of São Paulo State, Brazil, due to the convergence of a precipitating system and the transport of biomass burning aerosols. Smoke plumes originated from burning areas in both Brazilian and Bolivian Amazon Basin, and also from other parts of Bolivia, were captured by the South Atlantic Convergence Zone and brought over large cities in the Brazilian Southeast. A cold front induced moist marine air convergence, promoting cloud formation at lower and higher altitudes. An abnormal darkening of the sky and clouds was observed over the Metropolitan Area of São Paulo (MASP, -23.5505°, -46.6339°, 760 m asl), the most densely populated urban area in South America. Rainwater samples were collected during precipitation events. The samples presented an exceptionally darkened appearance and a characteristic odor of smoke. This event was referred to as the "black rain".

The objectives of this study are: (i) the physical (turbidity and microscopy) and chemical characterization (water-soluble ions, monosaccharides, and PAHs) of "black rain" water samples collected over the MASP after an intense biomass burning episode in several areas of South America hinterland, (ii) to analyze satellite imagery and air mass back trajectories, and (iii) to investigate the influence of biomass burning transported aerosols on the precipitation.

## **2. Materials and methods**

Four samples were collected during the "black rain" precipitation event on August 19<sup>th</sup>, 2019, in sites around the MASP: eastern and southern zones of São Paulo (EZ and SZ), Diadema (DI), and Santo André (SA) (Figure 1). The samples were collected in clean plastic bottles and since the event was unexpected these were the only samples available;

those were the few sites with a significant accumulation of precipitation on that day. In the next days after the event, five control samples were collected in different sites. Two control samples were taken in the northern and western zones of São Paulo (NZ and WZ1) on September 1<sup>st</sup>, 2019. Three other control samples were collected on the rooftop of the Institute of Chemistry building, at the University of São Paulo main campus (WZ2), in a large glass beaker cleaned with ultrapure water, on September 3<sup>rd</sup>, 5<sup>th</sup>, and 6<sup>th</sup>. Thymol (C<sub>10</sub>H<sub>14</sub>O) was added to all samples as a biocide, and they were kept at -18 °C until analysis. After defrosting, the samples were quickly transferred to glassware for analytical further procedures.

Sample Label	Date	Site	Sample type
EZ	19 <sup>th</sup> August	East Zone – São Paulo	Rain event
SZ	19 <sup>th</sup> August	South Zone – São Paulo	Rain event
DI	19 <sup>th</sup> August	Diadema	Rain event
SA	19 <sup>th</sup> August	Santo André	Rain event
NZ	1 <sup>st</sup> September	North Zone – São Paulo	Control
WZ1	1 <sup>st</sup> September	West Zone – São Paulo	Control
WZ2	3 <sup>rd</sup> September	West Zone 2 – São Paulo	Control
WZ2	5 <sup>th</sup> September	West Zone 2 – São Paulo	Control
WZ2	6 <sup>th</sup> September	West Zone 2 – São Paulo	Control

**Figure 1.** Sampling site locations and dates.

The “black rain” samples collected in three sites (DI, EZ, and SA) were freeze-dried to concentrate particulate matter for microscopic imaging. The images were obtained using a stereomicroscope Leica M205 FA, lens 1. The pictures were processed in the Leica Application Suite software (LAS-version 4.8).

Water-soluble ions were determined in duplicate;  $\text{Na}^+$ ,  $\text{K}^+$ ,  $\text{Ca}^{2+}$ ,  $\text{Mg}^{2+}$ ,  $\text{Cl}^-$ ,  $\text{SO}_4^{2-}$ , formate ( $\text{CHO}_2^-$ ), oxalate ( $\text{C}_2\text{O}_4^{2-}$ ), acetate ( $\text{C}_2\text{H}_3\text{O}_2^-$ ), fumarate ( $\text{C}_4\text{H}_2\text{O}_4^{2-}$ ), and glutarate ( $\text{C}_5\text{H}_6\text{O}_4^{2-}$ ). The samples were analyzed after filtration (Millipore Millex, 0.22  $\mu\text{m}$ ), with an ion chromatograph (Metrohm, Switzerland), the same equipment employed by Vasconcellos et al. (2010). For monosaccharide anhydrides (levoglucosan, mannosan, and galactosan), 25 mL aliquots of the samples were frozen in glass amber flasks with dry ice in an ethanol bath (-72 °C), and lyophilized for two days, similarly as described by Mullaugh et al. (2014). After the lyophilization, the particulate residue was extracted with a mixture containing 80 % of dichloromethane and 20 % of methanol (40 mL) for 1 h in an ultrasonic bath, then dried up with a rotary evaporator and derivatized with 40  $\mu\text{L}$  of a mixture of N-methyl-N-(trimethylsilyl)trifluoroacetamide (MSTFA) and pyridine (2:1; v/v) for 1 h, at 70 °C. After derivatization, the samples were analyzed in a gas chromatograph with a mass spectrometer detector (GC/MS). The extraction procedure of the particulate material was similar to that described in Pashynska et al. (2002). The recovery test was performed with the spiking of blank samples and the obtained values were 71, 91, and 94 %, for levoglucosan, mannosan, and galactosan.

For PAHs, a sample aliquot of 10 mL was inserted in a glass separatory funnel (pH between 6 and 10), then 100 mL of dichloromethane was added, and then the funnel was vigorously shaken for one minute, the procedure was repeated once more. The 200 mL

extract was dried up with rotary evaporation, and then the extracts were analyzed in a GC/MS (EMS Parameter, 2017).

The method accuracy was evaluated in two ways: by using certified reference material and performing recovery tests. The PAHs mixture was prepared with standard which contained the following compounds: fluorene (FLU), phenanthrene (PHE), anthracene (ANT), fluoranthene (FLT), pyrene (PYR), benzo[*a*]anthracene (BaA), chrysene (CHR), benzo[*b*]fluoranthene (BbF), benzo[*k*]fluoranthene (BkF), benzo[*a*]pyrene (BaP), indeno[1,2,3-*cd*]pyrene (InP), dibenzo[*a,h*]anthracene (DBA) and benzo[*ghi*]perylene (BPer) (610 mix, Supelco, USA), benzo[*e*]pyrene (BeP) (Supelco, USA) and coronene (COR) (Sigma-Aldrich, USA). All the samples were analyzed in triplicate, and the three samples collected in the university campus (WZ2) were pooled before extraction since the concentrations of PAHs were below the detection limit in those samples.

For the recovery test, three aliquots of standard solution were extracted and analyzed under the experimental conditions. Comparisons between the certified and the obtained values ranged from 84% (BkF) to 145% (FLT).

The solid material obtained from rainwater was freeze-dried and hydrolyzed with 1 mL of 2M trifluoroacetic acid (TFA) for 1 h at 100 °C. The samples were dried under vacuum and resuspended in 0.3 mL of deionized water. This was followed by filtration on 0.22µm (Merck Millipore) filters. The released monosaccharides were analyzed by HPAEC-PAD with a CarboPac SA10 column (ICS 5.000 system, Dionex-Thermo). The column was eluted isocratically with 99.2 % of water and 0.8 % (v/v) sodium hydroxide (1 mL min<sup>-1</sup>). The monosaccharides released from the cell wall were detected using a post-column base containing 500 mM NaOH (0.5 mL min<sup>-1</sup>) followed by a Pulsed

Amperometric Detector. The monosaccharide standards used were apiose, arabinose, fucose, galactose, glucose, mannose, rhamnose, and xylose (Pagliuso et al., 2018).

Turbidity was determined for the rain event samples SA, DI, and EZ, following the protocols described in Baird et al. (2017), with a Lovibond turbidimeter, TurbiCheck SN 13/39540. pH was determined using the multiparameter instrument Lovibond Senso Direct 150.

### **3. Results and discussions**

#### **3.1 Satellite imagery and long-range transport**

Satellite imagery from the National Oceanic and Atmospheric Administration's (NOAA) GOES-16 Advanced Baseline Instrument (ABI), and the National Aeronautics and Space Administration's (NASA) Moderate Resolution Imaging Spectroradiometer (MODIS) were recruited to help contextualize the synoptic outlook over the phenomenon area. Fig. 2 shows a large extent of cloud cover over the MASP, registered by both MODIS and ABI between 17:30 to 18:00 UTC (14:30 to 15:00 LT) when the onset of the anomalous sky darkening conditions was observed at the surface. Thick aerosol plumes are shown in Fig. 2 to the west and over the MASP, characterized by a distinct brownish tint over the cloud deck and other cloudless areas. A sequence of enhanced ABI images, every 10 minutes from 12:50 to 21:30 UTC (9:50 to 18:30 LT), is given in an external link<sup>1</sup>. The sequence highlights the prevalent easterly to the southeasterly movement of co-located clouds and heavy aerosol-carrying air masses during the event day. An extensive area can be identified west of the MASP where shallow convective clouds simultaneously develop and are transported eastward with the aerosol plumes, eventually forming a clumped cloud

<sup>1</sup> GOES-16 ABI sequence (48 MB): <https://bit.ly/2019-08-19-SP-GOES16>. Accessed May 30<sup>th</sup>, 2020 12:00 UTC.

220 deck cluster<sup>1</sup>. The cluster starts to cover the western outskirts of the MASP at about 16:50  
221 UTC (13:50 LT) and proceeds moving over the region past sunset time at 20:51 UTC  
222 (17:51 LT)<sup>1</sup>. This timing is concurrent with the initiation of the anomalous sky darkening  
223 conditions at about 17:30 UTC (14:30 LT), and the precipitation that followed 17:30 UTC  
224 to 21:30 UTC (Fig S3). During this period, Meteorological Aerodrome Reports (METAR)  
225 from the three airports in the MASP (SBSP, SBMT, and SBGR) indicate multiple layers of  
226 clouds, at about 152.4, 213.4, 914.4, and 3048.0 m above ground level (500, 700, 3,000 and  
227 10,000 ft).

228         The origin of the aerosol plumes identified in satellite imagery is discussed next.  
229 3,082 fire spots were detected<sup>2</sup> over the Brazilian Amazon by MODIS onboard the Aqua  
230 satellite in the 3-day period between August 17<sup>th</sup>, and 19<sup>th</sup>, 2019. During the same period,  
231 1,618 fire spots were detected in Bolivia<sup>2</sup>. On the days preceding the black-rain event,  
232 MODIS imagery identified thousands of fire spots and aerosol plumes over Bolivia and the  
233 Brazilian Amazon. Smoke from these fire spots was transported downwind, spreading over  
234 a large areal fraction of South America. About 24h before the event onset over the MASP  
235 MODIS captured a particularly severe burning area<sup>3</sup> over southeastern Bolivia  
236 (approximately at -19.1°N, -59.6°E), where numerous fire spots were detected, which  
237 produced vigorous biomass burning smoke plumes moving southeastward.

238         NOAA's Hysplit model (Rolph et al., 2017) was used to assess the relative  
239 contribution of air masses from different origins arriving at the MASP during the event.  
240 Ensembles of back trajectories were calculated starting at 250 m, 1000 m, and 3000 m

<sup>2</sup> <http://queimadas.dgi.inpe.br/queimadas/bdqueimadas>. Accessed May 30<sup>th</sup>, 2020 13:00 UTC.

<sup>3</sup> <https://go.nasa.gov/2TWk6hj> and <https://go.nasa.gov/3gGdy0d>. Accessed May 30<sup>th</sup>, 2020 14:00 UTC.

241 above ground level, and on 16Z, 18Z, and 20Z over MASP. Fig. 3 (left) shows one of such  
242 ensembles, and the others are shown in Fig. S1. These trajectories are compatible with the  
243 convergence of different air masses over the MASP and consistent with meteorological  
244 reports. Moist air masses arriving from the ocean were organized by a passing cold front,  
245 inducing low-level cloud formation. Air masses arriving over the MASP at mid-level (1-  
246 3km, Fig. S1) traveled from southern Amazon and Bolivia at a range of altitudes, some  
247 reaching lower levels in a smoke burdened atmospheric layer close to the surface, then  
248 were sharply taken aloft closer to the MASP, rising back to 1000-3000 m AGL over the  
249 cloud deck region shown in Fig. 2.

250 On the right side of Fig. 3 forward trajectories starting about 24h before the MASP  
251 event show the path followed by air masses originating over a region in Bolivia<sup>3</sup> heavily  
252 impacted by fires and smoke emitted from biomass burning. These trajectories, and those  
253 shown in Fig. S2, indicate the dense plumes of aerosol emission from this particular area in  
254 southeastern Bolivia may have had a significant impact on the MASP event.

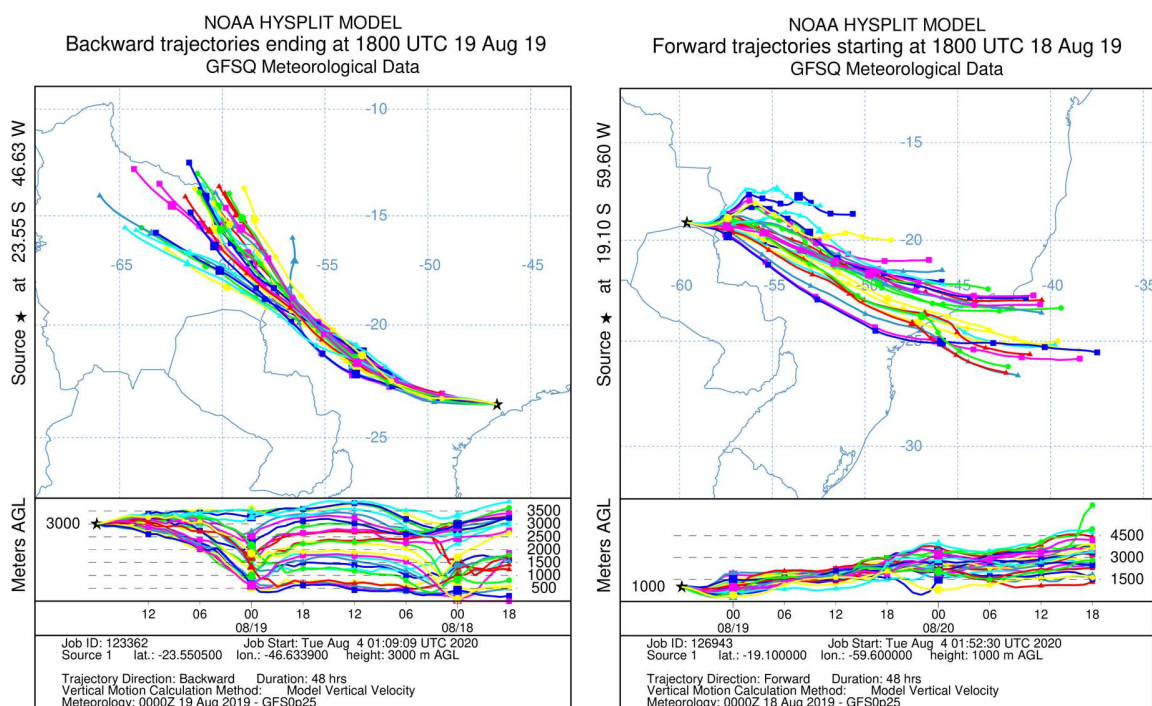

(a)

(b)

**Figure 2.** Satellite imagery over the Metropolitan Area of São Paulo (MASP; square). (a) Enhanced contrast National Oceanic and Atmospheric Administration's (NOAA) GOES-16 ABI at 2019-08-19 18:00 UTC indicates low-level clouds over the sampling area; (b) National Aeronautics and Space Administration's (NASA) Moderate Resolution Imaging Spectroradiometer (MODIS) onboard Aqua satellite at 17:30 UTC shows biomass burning smoke plumes covering large extents to the west of Sao Paulo State.

**Figure 3.** NOAA’s Hysplit model backward (left) and forward trajectories (right). Backward trajectories starting over the MASP indicate the convergence of moist low-level air masses coming from the ocean, and hotter, drier air masses aloft from the Amazon Basin and Bolivia, bringing smoke aerosol to the MASP. Forward trajectories starting over a Bolivian severe burning area about 24h before the event indicate aerosol plumes were transported toward the MASP. Other starting altitudes and times are shown in Fig S1 and S2.

### 3.2 Physical assessment

In the “black rain” samples collected in DI, SA, and EZ, the turbidity was estimated to be above 70 Nephelometric Turbidity Units (NTU). According to the United States Environmental Protection Agency (USEPA) guidelines, non-potable urban water for reuse should not present turbidity equal or higher than 2 NTU for 24 h periods, and not exceed 5 NTU any time (Mendez et al., 2011; USEPA, 2004). The freeze-dried materials in those samples were photographed (Fig. 4) showing that, at least for the water obtained from the collection at the SA and DI sites, some fibrous materials could be visualized, along with

particular material with the aspect of burned materials. Such fibers are likely to be part of plant materials such as fiber cells (or cell bundles) of the vascular system of trees and grasses that originated from incomplete combustion that ended up transported and precipitated with the rain. The chemical analyses of these materials, shown below, indicates that plant materials are indeed present and, besides chemical composition evidence (Section 3.4), These materials are the more likely to have maintained reasonable intact chemical structures due to the compactness and probably the hydration level of polymers in the vascular bundles and fibers of wood and leaves.

**Figure 4.** Freeze-dried solid materials obtained after freeze-drying the rainwater of the “black rain” that occurred on August 19<sup>th</sup> of 2019 in the Metropolitan Region of São Paulo. The materials are from the following localities: City of Santo André (SA) (a), East Zone of São Paulo City (EZ) (b), City of Diadema (DI) (c).

### 3.3 Water-soluble ions

The concentrations of water-soluble ions are presented in Table 1. In general, the most abundant cations were  $K^+$  and  $Ca^{2+}$  (total average of 165 and 228  $\mu\text{mol L}^{-1}$ , respectively), while the most abundant anions were  $Cl^-$  and  $SO_4^{2-}$  (total average of 98 and 33  $\mu\text{mol L}^{-1}$ , respectively). The species  $NH_4^+$ ,  $NO_2^-$ , and  $NO_3^-$  were not considered since they are observed in household cleaning products and part of the samples came from the household collection (all samples except the ones collected at WZ2). The average

concentrations of all ions except  $\text{Mg}^{2+}$ , formate ( $\text{CHO}_2^-$ ), and acetate ( $\text{C}_2\text{H}_3\text{O}_2^-$ ) were higher in the rainwater samples collected on August 19<sup>th</sup>, when the “black rain” episode was observed. Organic species, as formate and acetate, are biodegradable (Vet et al., 2014), which may affect their concentration in the samples. Some ionic species as  $\text{Mg}^{2+}$  can be related to other sources in the site, such as soil dust and urban dust surface resuspension (Rocha et al., 2003). The ionic species concentrations reduced after the event. The measured pH values during the event were 8.2, 7.5, and 7.1 for the EZ, DI, and SA samples, respectively; not acidic.

**Table 1:** Water-soluble ions concentrations ( $\mu\text{mol L}^{-1}$ ) and depositions, in parentheses ( $\text{mg m}^{-2}$ ), for all rainwater samples, including periods during and after the “black rain” event. Avg. BR = Average during the “black rain” event. Avg. NR = Average during normal rain events. <LOD = Below limit of detection. <LOQ = Below limit of quantification. Depositions fluxes were considered as zero when concentrations were below the detection and/or quantification limits.

Species as  $K^+$  and  $Cl^-$  can be observed in the particulate matter emitted in the process of biomass burning (Allen et al., 2004; Pereira et al., 2017b), and more soluble particulate matter can act as cloud condensation nuclei and form cloud droplets (Seinfeld, 2004), carrying these species. Potassium maximum monthly concentration has been observed in the dry periods in São Paulo in a previous study that took place between 2002 and 2005, and its presence was partly attributed to biomass burning (Vieira-Filho et al., 2013); in that previous study, sulfate has been observed as a dominant species and related mostly to anthropogenic emission processes in the metropolitan area of São Paulo, the average concentration of potassium and sulfate were of 4.89 and 16.7  $\mu\text{mol L}^{-1}$ , respectively. Potassium concentration in Vieira-Filho et al. (2013) reached a value of 10.9  $\mu\text{mol L}^{-1}$  during excess events, much lower than the values observed in the dark rainwater event (range of 41 - 402  $\mu\text{mol L}^{-1}$ ).

The ratio  $[K^+]/[SO_4^{2-}]$  was above or equal to 1.5 in the collected “black rain” samples; this value has been associated by Vieira-Filho et al. (2013) to long-range transport of pollutants in the rainwater. In that previous study, transport of air masses from the interior of Brazil (including São Paulo state) was observed, leading to higher levels of potassium concentrations;  $K^+$  concentrations were directly proportional to the observed fire spot numbers. Trajectories pointed to transport from the Midwest and North of Brazil that comprises several states in the termed “arc of deforestation”, since many fires related to forest burning are registered there, mainly in the drier months (from June to October) (de Oliveira Alves et al., 2011).

Daily deposition flux was calculated with precipitation data derived from different satellites (CHIRPS, CMORPH, and TRMM) and the weather radar; the species concentrations were multiplied by the rainfall amount, similarly as in Roy et al. (2019).

Since the precipitation was much lower during the event, most of the ion depositions were higher after the event than during it. The average daily depositions for sulfate and potassium during the “black rain” event were of 18 and 31 mg m<sup>-2</sup>, respectively, and in the following samples, of 42 and 74 mg m<sup>-2</sup>, respectively.

Potassium is related to biomass and biogenic processes in wet and dry deposition (Pauliquevis et al., 2012; Vieira-Filho et al., 2013), the species’ deposition flux presented a reduction after the event, with lowest values observed in WZ and WZ2, although there was an outlier (NZ) where a very high deposition was observed, 337 mg m<sup>-2</sup>. Wet deposition of non-sea salt sulfur (which includes sulfate) is typically higher in southeastern Brazil, and lower in the remote areas of Amazonia (Vet et al., 2014). The observed sulfate in São Paulo rainwater is more associated with secondary reactions of SO<sub>2</sub> emitted by vehicles and has decreased in the previous decades (Fornaro and Gutz, 2006).

If we extrapolate the results presented in this study, the yearly deposition for sulfate and potassium during the black rainwater event would be of 6.4 and 11.4 g m<sup>-2</sup> yr<sup>-1</sup>; in a previous study, performed two decades ago, the wet deposition observed in São Paulo for sulfate and potassium were of 2.5 and 0.35 g m<sup>-2</sup> yr<sup>-1</sup> (Rocha et al., 2003), it is possible to observe much higher potassium deposition during the event in the present study.

### **3.4 Plant biomass and biomass burning tracers**

The samples collected on August 19<sup>th</sup>, during the “black rain” event, presented much higher concentrations of levoglucosan than in the other days (Fig. 5), with an average of 0.33 and 0.02 µg mL<sup>-1</sup>, respectively. The higher levels of these tracers suggest a greater influence of biomass burning aerosols during the event (Mullaugh et al., 2014). The highest levoglucosan concentrations were observed at the cities of Diadema and Santo André, both

east of the Metropolitan Area of São Paulo, reaching values of 0.31 and 0.67  $\mu\text{g mL}^{-1}$ , respectively. In a previous study performed in the Amazon region (dry period), the levoglucosan concentration reached a higher value of 1.5  $\mu\text{g mL}^{-1}$  (qualitative) (Schkolnik et al., 2005). The presence of the monosaccharide anhydride was attributed to in-cloud processes related to biomass burning aerosols, by mixing of cloud droplets and smoke particles or droplet nucleation on smoke particles, although it also could be attributed to rain scavenging.

The daily average deposition flux for levoglucosan was more than three times higher during the black rain event, of 1.04  $\text{mg m}^{-2}$  (ranging from 0.32 to 1.82  $\text{mg m}^{-2}$ ), after the event the average was of 0.31  $\text{mg m}^{-2}$  (ranging from 0.02 to 0.64  $\text{mg m}^{-2}$ ) (Fig. 5). The ratio between the depositions of levoglucosan and  $\text{SO}_4^{2-}$  was proposed by the authors to understand the influence of biomass burning in the rainwater samples in the present study, since sulfate in São Paulo is more related to a secondary formation from precursor  $\text{SO}_2$  emitted by vehicles (Rocha et al., 2003); the ratio was of 0.08 during the event and of 0.02 after it, corroborating to a higher biomass burning influence in the dark rainwater samples.

**Figure 5.** Levoglucosan concentrations and daily deposition fluxes (bars and squares, respectively) of rainwater samples collected at SPMA during the “black rain” event (inside the square) and after.

Mannosan and galactosan were detected in all samples collected during the “black rain” event (average concentrations of 0.07 and 0.05  $\mu\text{g mL}^{-1}$ , respectively), and could not be quantified in most of the post-event rainwater (North Zone, 01 September); it was not possible to associate Lev/Man ratio to sources since it varied between 1.0 and 8.5 in the “black rain” samples).

Cell wall monosaccharides were determined (fucose, arabinose, galactose, rhamnose, glucose, xylose, and mannose) and are presented in Table 2. The combination of monosaccharides found is typical of higher plants (Buckeridge, 2018), indicating that plant materials are present in the particulate matter that precipitated with rainwater during the “black rain”. Although the small amount of dry material did not afford the calculation of monosaccharides per mass of particulate matter, Table 2 shows that glucose, probably from cellulose, xylose, and mannose are the most abundant components. Galactose, arabinose,

fucose, and rhamnose are also present as less abundant compounds. These results suggest that the major components are cellulose, xylans, and mannans (Schädel et al., 2010; Souza et al., 2013). These polymers are typical components of the wood and plant materials, being present in vascular systems of woods and leaves of trees, including palm trees (mannans) (Carpita and Gibeaut, 1993). The less abundant compounds (arabinose, galactose, fucose, and rhamnose) are also evidence of the presence of plant materials present in the cell walls of plants because they are typical components of pectin polymers (Schädel et al., 2010; Souza et al., 2013). Thus, the observation of fibers in microscopic views (Fig. 4) and the sugar composition of the freeze-dried materials (Table 2) are indicative that the particulate matter brought from the South American hinterland and that precipitated as the “black rain” in São Paulo are a result of partially combusted plant materials.

**Table 2.** Monosaccharide composition of the particulate matter obtained from the black rain in the Metropolitan Region of São Paulo ( $\mu\text{g}$  of sugar hydrolyzed per 300 $\mu\text{L}$  of water) on sites EZ, DI, and SA (August 19<sup>th</sup>). The composition was obtained after hydrolysis with trifluoroacetic acid followed by High-Performance Anion-Exchange Chromatography (HPAEC) with Pulsed Amperometric Detection (PAD).

( $\mu\text{g}$ sugar per 300 $\mu\text{L}$ of water)	Fucose	Arabinose	Galactose	Rhamnose	Glucose	Xylose	Mannose
<b>EZ</b>	3.5	6.8	12.8	4.4	19.8	10.4	11.5
<b>DI</b>	3.9	13.3	12.7	3.0	47.7	13.6	12.9
<b>SA</b>	9.9	19.2	19.1	10.0	90.9	87.7	35.8

### 3.5 Polycyclic aromatic hydrocarbons

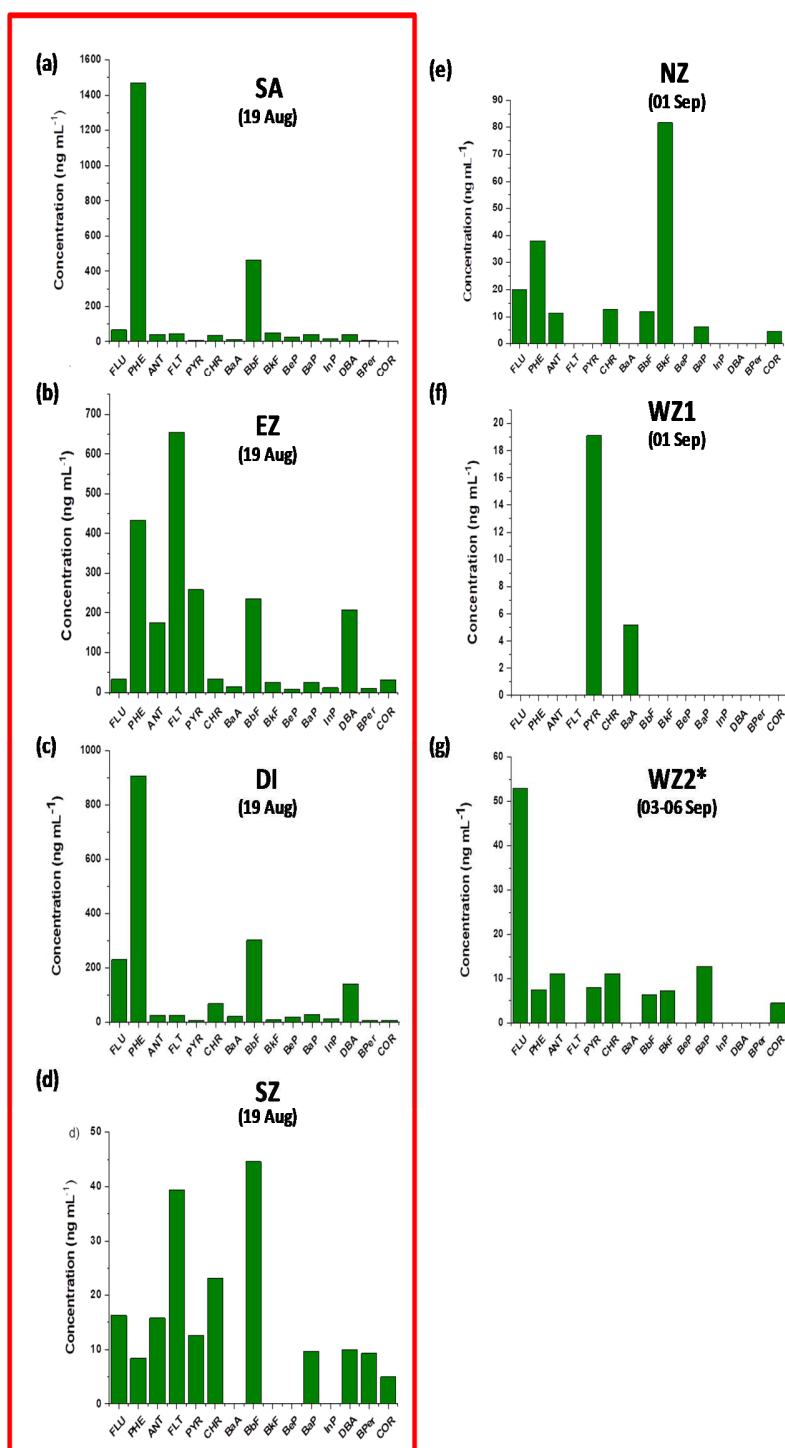

The results of the 15 PAHs compounds analyzed in rainwater in SPMA are summarized in Fig. 6.  $\Sigma\text{PAHs}$  concentrations were one hundred times higher for the samples collected during the “black rain” event (EZ = 2155 ng mL<sup>-1</sup>, SA = 2322 ng mL<sup>-1</sup>, DI = 1810 ng mL<sup>-1</sup>, SZ = 194 ng mL<sup>-1</sup>) than the regular rainy days (WZ1 = 24 ng mL<sup>-1</sup>,

WZ2\* = 122 ng mL<sup>-1</sup>, NZ = 187 ng mL<sup>-1</sup>);  $\Sigma$ PAHs also presented higher deposition flux during the event (5.1 and 2.7 mg m<sup>-2</sup>, respectively). Among the PAHs classified as carcinogenic by IARC (2010), BaP was detected in high quantities in all samples collected during the event (Fig. 6A, 6B, 6C, and 6D) and in other two samples of the regular days (Fig. 6E, 6F, and 6G). The sample collected at East Zone (EZ, Fig. 6A) showed a predominance of FLT (653 ng mL<sup>-1</sup>), PHE (433 ng mL<sup>-1</sup>), and PYR (258 ng mL<sup>-1</sup>). For the rainwater collected at Santo André city (SA, Fig. 6B), in MASP, the most abundant PAHs were PHE (1467 ng mL<sup>-1</sup>), BbF (464 ng mL<sup>-1</sup>), and FLU (67 ng mL<sup>-1</sup>). Following, another sample collected at MASP, in Diadema city (DI, Fig. 6C), showed a high concentration of PHE (905 ng mL<sup>-1</sup>), BbF (302 ng mL<sup>-1</sup>), and FLU (229 ng mL<sup>-1</sup>). The last sample collected during the “black rain” was from the South Zone of SP (SZ, Fig. 6D), and its dominant compounds were BbF (44 ng mL<sup>-1</sup>), FLT (39 ng mL<sup>-1</sup>), and CHR (23 ng mL<sup>-1</sup>).

Retene, a marker of biomass burning, was qualitatively identified in all four samples collected during the “black rain” episode (Ramdahl, 1983), by injection of a solution of qualitative retene standard, which allowed searching this compound in the samples. This species has been found as the most abundant PAH in particulate matter during dry season biomass burning episodes in the Amazon region and attributed to DNA damage and cell death *in vitro* (de Oliveira Alves et al., 2014, 2011; de Oliveira Alves et al., 2017). In particulate matter, the predominance of the low molecular weight (LMW) PAHs PHE, FLT, and PYR may indicate an influence of biomass burning emissions (Simoneit, 2002). On average, PHE, FLT, and PYR presented higher deposition fluxes during the event; the fluxes during the event were of 2.3, 0.5, and 0.19 mg m<sup>-2</sup>, respectively, and after were of 0.4, 0.2 and 0.05 mg m<sup>-2</sup>. Among the high molecular weight (HMW) PAHs there was a predominance of BbF; this species is cited as a probable human carcinogen and found in

442 particulate matter from vehicular emissions (Pereira et al., 2017b; Ravindra et al., 2008).  
443 Particulate organic pollutants as PAHs can be deposited in the soil, vegetation, and waters  
444 after wet deposition by precipitation, bringing risks to terrestrial and aquatic life (Malik et  
445 al., 2007; Olivella, 2006).

446

447 **Figure 6.** PAHs concentrations of rainwater samples collected at SPMA during the “black  
 448 rain” event (inside the square) and after. The three samples collected at WZ2\* were pooled  
 449 for this analysis.

Concerning the rainwater collected in September, the one collected at the West Zone of São Paulo City (WZ1, Fig. 5E) presented only two between fifteen PAHs possible to determine, which were FLT (19 ng mL<sup>-1</sup>), and CHR (5 ng mL<sup>-1</sup>). In the other samples collected at West Zone (WZ2\*, Fig. 6F), nine PAHs were determined, which were FLU (53 ng mL<sup>-1</sup>), BaP (13 ng mL<sup>-1</sup>), and CHR (11 ng mL<sup>-1</sup>), also retene was not found in this sample. Lastly, in the North Zone (NZ, Fig. 6G), the rainwater contained eight in fifteen PAHs, and the dominant species were BkF (82 ng mL<sup>-1</sup>), PHE (38 ng mL<sup>-1</sup>), and FLU (20 ng mL<sup>-1</sup>), this time, the retene was identified.

The tendency of the predominance of some PAHs, such as PHE, PYR, FLT, and FLU, was observed in previous studies conducted with rainwater collected in urban areas (Delhomme et al., 2008; Huybrechts et al., 2016). Although it is difficult to compare values obtained in the present work with other studies since the atypical event occurred in MASP in August, the concentrations were high compared to results obtained during polluted events in France (Delhomme et al., 2008) and India (Malik et al., 2007), the sampling and analytical methods do not allow a direct comparison. In rainwater collected at a subalpine area in Northern Italy, from July 2003 and January 2004, the most abundant compounds were BaA (18.4 x 10<sup>-3</sup> ng mL<sup>-1</sup>) and FLT (17.2 x 10<sup>-3</sup> ng mL<sup>-1</sup>) (Olivella, 2006), which are one thousand times lower than the present study; another study conducted with rainwater runoff from recovery and recycling companies in Flanders region (Belgium) presented a PHE maximum concentration of 130 ng mL<sup>-1</sup>, as well as FLT maximum concentration of 88 ng mL<sup>-1</sup> (Huybrechts et al., 2016), these values were similar to those obtained in this work.

Further, the lower molecular weight (LMW) PAHs dominated over the high molecular weight (HMW) compounds (Fig. 7). In the atmosphere, HMW-PAHs (with four

or more aromatic rings), such as benzo[*a*]pyrene, are dominant in the particulate matter (PM) due to their low vapor pressure. In contrast, LMW-PAH (with three or fewer aromatic rings) are more abundant in the gaseous phase, where they react with other pollutants such as ozone and NO<sub>x</sub> to form more toxic compounds. Both gaseous and particulate PAHs can be removed by wash-out (below cloud scavenging) and rain out (in-cloud scavenging) (Cousins et al., 1999; Liu et al., 2015; Park et al., 2001; Ravindra et al., 2008), which may have occurred in the contact of the different air masses during that event. For the samples collected during the “black rain” (EZ, SA, DI, and SZ), compounds with three or four rings were more predominant than those with five and six rings, indicating that PAHs in the gaseous phase (three rings) may have been removed by rain-out and wash-out. In the gas phase, SVOC with lower Henry’s Law constants, as LMW-PAHs, are more scavenged by precipitation (Cousins et al., 1999). Additionally, PAHs with four rings can be found in both particulate and gaseous phases and showed a great contribution. This may occur due to the physical-chemical properties of the compounds. For example, the water solubility is higher for the lower molecular weight PAHs than for the higher molecular weight PAHs (Malik et al., 2007).

**Figure 7.** PAHs concentration for three, four, five, and six rings collected in the “black rain” event and after. The three samples collected at WZ2\* were pooled for this analysis.

The ratio between PAHs can be useful for sources apportionment, for instance, being used to detect combustion-derived aerosols. In general, combustion and/or anthropogenic aerosols are frequently inferred from a rise in the fraction of the less stable PAHs, so the ratio between isomers can support the source identification (Yunker et al., 2002). Table S1 shows the calculated ratios for the present study comparing to the literature values. FLT/(FLT+PYR) ratios, ranged from 0.72 to 0.86 for the rainwater collected in the “black rain” event. Aerosols from urban regions presented values between 0.52 and 0.56, while the value for bush fire particulate matter was of 0.61 (Freeman and Cattell, 1990; Yunker et al., 2002). Darkened rain samples presented a high range of values compared to literature, while for regular rain days it was not possible to calculate this ratio because the concentration of these PAHs had been under the detection limit. This finding probably shows a unique profile concerning forest fires’ contributions to wet deposited PAHs. According to previous studies, InP/(InP+BPer) ratios vary less in urban locations than in

remote areas. The present work found InP/(InP+BPer) ratios near bush fire particulate matter (0.70) (Freeman and Cattell, 1990; Yunker et al., 2002).

#### 4. Conclusions

An unforeseen darkened rainwater event was observed on August 19<sup>th</sup>, 2019 throughout the Metropolitan Area of São Paulo, and the collected samples were physically and chemically characterized and compared to control samples from after that event. On that day, winds transported thick plumes of biomass burning aerosols from both Brazilian and Bolivian Amazon Basin and also in other areas in Bolivia; these air masses converged over the MASP darkening the early afternoon sunlight when the dark rain event was registered, as it was observed by a sequence<sup>4</sup> of satellite imagery. These darkened rainwater samples presented high turbidity and fibrous structures were observed together with particulate material with a burned aspect, after freeze-drying; in these freeze-dried particles, glucose (derived from cellulose), xylose, and mannose were the most abundant monosaccharides, corroborating the influence of partially combusted plant materials. Other chemical pieces of evidence of the influence of biomass burning emissions were found, the samples collected during the event presented much higher concentrations of tracers as potassium, levoglucosan, mannosan, and galactosan than the control samples; the deposition flux of organic biomass burning tracers was more than three times higher during the event. It was observed that the “black rain” samples presented increased PAHs concentrations if compared to posterior rain events, these species also presented a higher deposition flux during the event. Some of the detected PAHs (retene and

<sup>4</sup> <https://bit.ly/2019-08-19-SP-GOES16>. Accessed May 30th, 2020 12:00UTC.

benzo[*b*]fluoranthene) have been previously related to adverse health effects; these organic pollutants can contaminate soil, vegetation, and waters after wet deposition by precipitation. The results are of great concern since increased forest fires and deforestation are associated with climate change and the long-range transport of aerosols can affect different countries in the subcontinent (Brazil and Bolivia), leading to public health impacts.

## **5. Competing interests**

The authors declare that they have no conflict of interest.

## **6. Acknowledgments.**

The authors gratefully acknowledge the NOAA Air Resources Laboratory (ARL) for the provision of the HYSPLIT transport and dispersion model and READY website (<https://www.ready.noaa.gov>) used in this publication. The authors thank FAPESP (2010/15959-3, 2016/23339-1, 2016/18866-2, 2018/16608-1, 2019/01316-8, and 2019/13936-0), São Paulo Research Foundation, and CNPq (308682/20173, 301503/2018-4, 429112/2018-1, and 120779/2019-6), National Council for Scientific and Technological Development. This work was also supported by the National Institute of Science and Technology of Bioethanol (INCT-Bioethanol) (FAPESP 2008/57908-6 and 2014/50884-5; CNPq 574002/2008-1 and 465319/2014-9). The authors thank Professor Theotonio Mendes Pauliquevis Júnior for reviewing and suggesting important improvements to this paper.
